AUTOMOTIVE TECHNOLOGY:**A Systems Approach, 5e**

Jack Erjavec

Vice President, Career and Professional
Editorial: Dave Garza

Director of Learning Solutions: Sandy Clark

Executive Editor: David Boelio

Managing Editor: Larry Main

Senior Product Manager: Matthew Thouin

Editorial Assistant: Lauren Stone

Vice President, Career and Professional
Marketing: Jennifer McAvey

Executive Marketing Manager: Deborah S. Yarnell

Senior Marketing Manager: Jimmy Stephens

Marketing Specialist: Mark Pierro

Production Director: Wendy Troeger

Production Manager: Mark Bernard

Content Project Manager: Cheri Plasse

Art Director: Benj Gleeksman

SECTION 1 AUTOMOTIVE TECHNOLOGY

1

CHAPTER 1 Careers in the Automotive Industry 1

Objectives 1 ■ The Automotive Industry 1 ■ Job Classifications 9 ■ Related Career Opportunities 12

■ Training for a Career in Automotive Service 14 ■ ASE Certification 15 ■ Key Terms 16 ■ Summary 16 ■ Review Questions 17

CHAPTER 2 Workplace Skills 19

Objectives 19 ■ Seeking and Applying for Employment 19 ■ Accepting Employment 26 ■ Working as a Technician 27 ■ Communications 29 ■ Solving Problems and Critical Thinking 31 ■ Professionalism 32 ■ Interpersonal Relationships 34 ■ Key Terms 34 ■ Summary 34 ■ Review Questions 35

CHAPTER 3 Automotive Systems 37

Objectives 37 ■ Historical Background 37 ■ Design Evolution 38 ■ Body Shapes 39 ■ The Basic

Engine 41 ■ Engine Systems 43 ■ Electrical and Electronic Systems 46 ■ Heating and Air-Conditioning Systems 49 ■ Drivetrain 50 ■ Running Gear 53 ■ Hybrid Vehicles 55 ■ Key Terms 56 ■ Summary 56 ■ Review Questions 57

CHAPTER 4 Hand Tools and Shop Equipment 59

Objectives 59 ■ Measuring Systems 59 ■ Fasteners 60 ■ Measuring Tools 67 ■ Hand Tools 75 ■ Shop Equipment 86 ■ Power Tools 88 ■ Jacks and Lifts 89 ■ Service Information 92 ■ Key Terms 96 ■ Summary 96 ■ Review Questions 96

CHAPTER 5 Diagnostic Equipment and Special Tools 99

Objectives 99 ■ Engine Repair Tools 99 ■ Electrical/Electronic System Tools 106 ■ Engine Performance Tools 110 ■ Transmission and Driveline Tools 119 ■ Suspension and Steering Tools 121 ■ Brake System Tools 124 ■ Heating and Air-Conditioning Tools 128 ■ Key Terms 131 ■ Summary 131 ■ Review Questions 132

CHAPTER 6 Working Safely in the Shop 134

Objectives 134 ■ Personal Safety 134 ■ Tool and Equipment Safety 138 ■ Work Area Safety 144 ■ Manufacturers' Warnings and Government Regulations 148 ■ Right-to-Know Law 148 ■ Key Terms 151 ■ Summary 151 ■ Review Questions 151

CHAPTER 7 Preventive Maintenance and Basic Services 153

Objectives 153 ■ Repair Orders 153 ■ Vehicle Identification 156 ■ Preventive Maintenance 157 ■ Basic Services 159 ■ Hybrid Vehicles 180

■ Additional PM Checks 182 ■ Key Terms 182 ■ Summary 183 ■ Review Questions 183

CHAPTER 8 Basic Theories and Math 186

Objectives 186 ■ Matter 186 ■ Energy 188 ■ Volume 191 ■ Force 193 ■ Time 195 ■ Motion 195 ■ Work 197 ■ Waves and Oscillations 202 ■ Light 205 ■ Liquids 205 ■ Gases 207 ■ Heat 209 ■ Chemical Properties 211 ■ Electricity and Electromagnetism 215 ■ Key Terms 216 ■ Summary 217 ■ Review Questions 219

SECTION 2 ENGINES

220

CHAPTER 9 Automotive Engine Designs and Diagnosis 220

Objectives 220 ■ Introduction to Engines 220 ■ Engine Classifications 221 ■ Engine

Measurement and Performance 228 ■ Diesel Engines 232 ■ Other Automotive Power Plants 236 ■ Engine Identification 240 ■ Engine Diagnostics 241 ■ Evaluating the Engine's Condition 247 ■ Noise Diagnosis 249 ■ Case Study 252 ■ Key Terms 252 ■ Summary 252 ■ Review Questions 253 ■ ASE-Style Review Questions 254

■ Review Questions 320 ■ ASE-Style Review Questions 321

CHAPTER 12 Upper End Theory and Service 322

Objectives 322 ■ Cylinder Head 322 ■ Combustion Chamber 323 ■ Intake and Exhaust Valves 324 ■ Variable Valve Timing 330 ■ Cylinder Head Disassembly 335 ■ Inspection of the Valve Train 339 ■ Servicing Cylinder Heads 344 ■ Reconditioning Valves 347 ■ Valve Guide Reconditioning 349 ■ Reconditioning Valve Seats 351 ■ Valve Stem Seals 354 ■ Assembling the Cylinder Head 355 ■ Case Study 356 ■ Key Terms 358 ■ Summary 358 ■ Review Questions 358 ■ ASE-Style Review Questions 359

CHAPTER 10 Engine Disassembly and Cleaning 255

Objectives 255 ■ Removing an Engine 255 ■ Engine Disassembly and Inspection 262 ■ Cleaning Engine Parts 264 ■ Crack Detection 269 ■ Case Study 271 ■ Key Terms 272 ■ Summary 272 ■ Review Questions 272 ■ ASE-Style Review Questions 273

CHAPTER 11 Lower End Theory and Service 275

Objectives 275 ■ Short Block Disassembly 276 ■ Cylinder Block 279 ■ Cylinder Block Reconditioning 281 ■ Camshafts 285 ■ Crankshaft 292 ■ Crankshaft Inspection and Rebuilding 294 ■ Installing Main Bearings and Crankshaft 296 ■ Piston and Piston Rings 302 ■ Installing Pistons and Connecting Rods 307 ■ Inspection of Camshaft and Related Parts 310 ■ Installation of Camshaft and Related Parts 311 ■ Crankshaft and Camshaft Timing 312 ■ Oil Pumps 313 ■ Oil Pump Service 315 ■ Installing the Oil Pump 318 ■ Case Study 318 ■ Key Terms 319 ■ Summary 319

CHAPTER 13 Engine Sealing and Reassembly 361

Objectives 361 ■ Torque Principles 361 ■ Gaskets 364 ■ Specific Engine Gaskets 367 ■ Adhesives, Sealants, and Other Chemical Sealing Materials 371 ■ Oil Seals 374 ■ Engine Reassembly 375 ■ Installing the Engine 385 ■ Case Study 390 ■ Key Terms 390 ■ Summary 390 ■ Review Questions 391 ■ ASE-Style Review Questions 391

CHAPTER 14 Lubricating and Cooling Systems 393

Objectives 393 ■ Lubrication System 393 ■ Engine Lubrication Diagnosis and Service 398 ■ Cooling Systems 400 ■ Cooling System Diagnosis 409 ■ Inspection of Cooling System 411 ■ Testing for Leaks 416 ■ Cooling System Service 420 ■ Case Study 429 ■ Key Terms 430 ■ Summary 430 ■ Review Questions 431 ■ ASE-Style Review Questions 432

SECTION 3 ELECTRICITY**433****CHAPTER 15
Basics of Electrical
Systems 433**

Objectives 433 ■ Basics of Electricity 433 ■ Electrical Terms 435 ■ Ohm's Law 438 ■ Circuits 440 ■ Circuit

Components 444 ■ Key Terms 454 ■ Summary 454 ■ Review Questions 455 ■ ASE-Style Review Questions 455

**CHAPTER 16 General
Electrical System Diagnostics
and Service 457**

Objectives 457 ■ Electrical Problems 457 ■ Electrical Wiring Diagrams 460 ■ Electrical Testing Tools 461 ■ Using Multimeters 465 ■ Using Lab Scopes 474 ■ Testing Basic Electrical Components 478 ■ Troubleshooting Circuits 482 ■ Testing for Common Problems 486 ■ Connector and Wire Repairs 490 ■ Case Study 497 ■ Key Terms 498 ■ Summary 498 ■ Review Questions 498 ■ ASE-Style Review Questions 499

**CHAPTER 17 Batteries: Theory,
Diagnosis, and Service 501**

Objectives 501 ■ Introduction 501 ■ Basic Battery Theory 501 ■ Battery Ratings 504 ■ Common Types of Batteries 505 ■ High-Voltage Batteries 507 ■ Lead-Acid Batteries 507 ■ Servicing and Testing Batteries 513 ■ Nickel-Based Batteries 524 ■ Lithium-Based Batteries 526 ■ Isolating High-Voltage Systems 528 ■ Jump-Starting 530 ■ Case Study I 532 ■ Case Study II 532 ■ Key Terms 533 ■ Summary 533 ■ Review Questions 534 ■ ASE-Style Review Questions 534

**CHAPTER 18 Starting and
Traction Motor Systems 536**

Objectives 536 ■ Basics of Electromagnetism 536 ■ Starting Motors 539 ■ Starting System 542 ■ Starter Circuit 543 ■ Control Circuit 546 ■ Starting System Testing 547 ■ Starter Motor Service 554 ■ Case Study 558 ■ High-Voltage Motors 560 ■ Key Terms 567 ■ Summary 567 ■ Review Questions 568 ■ ASE-Style Review Questions 569

**CHAPTER 19 Charging
Systems 571**

Objectives 571 ■ Alternating Current Charging Systems 571 ■ AC Generator Operation 575 ■ Voltage

Regulation 577 ■ New Developments 580 ■ Preliminary Checks 582 ■ General Testing Procedures 586 ■ AC Generator Service 588 ■ Case Study 593 ■ Key Terms 593 ■ Summary 593 ■ Review Questions 593 ■ ASE-Style Review Questions 594

**CHAPTER 20 Lighting
Systems 596**

Objectives 596 ■ Lamps 596 ■ Headlights 597 ■ Headlight Service 605 ■ Other Light Bulbs 610 ■ Interior Light Assemblies 610 ■ Rear Exterior Lights 612 ■ Basic Lighting System Diagnosis 619 ■ Case Study 621 ■ Key Terms 621 ■ Summary 621 ■ Review Questions 621 ■ ASE-Style Review Questions 622

**CHAPTER 21 Electrical
Instrumentation 624**

Objectives 624 ■ Instrument Panels 624 ■ Gauges 625 ■ Basic Information Gauges 627 ■ Indicator and Warning Devices 630 ■ Driver Information Centers 635 ■ General Diagnosis and Testing 637 ■ Case Study 637 ■ Key Terms 637 ■ Summary 637 ■ Review Questions 638 ■ ASE-Style Review Questions 639

**CHAPTER 22 Basics of
Electronics and Computer
Systems 640**

Objectives 640 ■ Capacitors 640 ■ Semiconductors 642 ■ Computer Basics 646 ■ On-Board Diagnostics 656 ■ Multiplexing 658 ■ Protecting Electronic Systems 662 ■ Diagnosing BCMs 663 ■ Testing Electronic Circuits and Components 664 ■ Key Terms 667 ■ Summary 667 ■ Review Questions 668 ■ ASE-Style Review Questions 669

**CHAPTER 23 Electrical
Accessories 670**

Objectives 670 ■ Windshield Wiper/Washer Systems 670 ■ Horns/Clocks/Cigarette Lighter Systems 677 ■ Cruise (Speed) Control Systems 678 ■ Sound Systems 682 ■ Power Lock Systems 684 ■ Power Windows 684 ■ Power Seats 687 ■ Power Mirror System 690 ■ Rear-Window Defrosters and Heated Mirror Systems 691 ■ Other Electronic Equipment 692 ■ Security and Antitheft Devices 697 ■ Case Study 700 ■ Key Terms 701 ■ Summary 701 ■ Review Questions 701 ■ ASE-Style Review Questions 702

CHAPTER 24 Restraint Systems: Theory, Diagnosis, and Service 704

Objectives 704 ■ Seat Belts 704 ■ Seat Belt Service 706 ■ Air Bags 708 ■ Electrical System

Components 712 ■ Diagnosis 716 ■ Servicing the Air Bag System 718 ■ Other Protection Systems 719 ■ Case Study 722 ■ Key Terms 722 ■ Summary 722 ■ Review Questions 723 ■ ASE-Style Review Questions 724

SECTION 4 ENGINE PERFORMANCE

725

CHAPTER 25 Engine Performance Systems 725

Objectives 725 ■ Ignition Systems 725 ■ Fuel System 728 ■ Air Induction System 729 ■ Emission Control Systems 729

■ Engine Control Systems 731 ■ On-Board Diagnostic Systems 736 ■ System Operation 739 ■ OBD-II Monitoring Capabilities 740 ■ OBD-II Self-Diagnostics 747 ■ Basic Diagnosis of Electronic Engine Control Systems 749 ■ Diagnosing OBD-II Systems 751 ■ Diagnosing OBD-I Systems 759 ■ Case Study 760 ■ Key Terms 760 ■ Summary 760 ■ Review Questions 761 ■ ASE-Style Review Questions 762

CHAPTER 26 Detailed Diagnosis and Sensors 764

Objectives 764 ■ Using Scan Tool Data 764 ■ Symptom-Based Diagnosis 768 ■ Basic Testing 770 ■ Diagnosis of Computer Voltage Supply and Ground Wires 771 ■ Switches 774 ■ Temperature Sensors 775 ■ Pressure Sensors 778 ■ Mass Airflow (MAF) Sensors 783 ■ Oxygen Sensors (O₂S) 785 ■ Position Sensors 794 ■ Speed Sensors 797 ■ Position/Speed Sensors 799 ■ Knock Sensor (KS) 802 ■ Computer Outputs and Actuators 803 ■ Testing Actuators 804 ■ Case Study 807 ■ Key Terms 807 ■ Summary 807 ■ Review Questions 808 ■ ASE-Style Review Questions 808

CHAPTER 27 Ignition Systems 810

Objectives 810 ■ Basic Circuitry 810 ■ Ignition Components 813 ■ Spark Plugs 815 ■ Triggering and Switching Devices 819 ■ Engine Position Sensors 820 ■ Distributor Ignition System Operation 822 ■ Electronic Ignition Systems 823 ■ EI System Operation 827 ■ Case Study 832 ■ Key Terms 833 ■ Summary 833 ■ Review Questions 833 ■ ASE-Style Review Questions 834

CHAPTER 28 Ignition System Diagnosis and Service 836

Objectives 836 ■ Misfires 836 ■ General Ignition System Diagnosis 837 ■ Visual Inspection of Ignition Systems 837 ■ No-Start Diagnosis 842 ■ Diagnosing with an Engine Analyzer 844 ■ Diagnosing with a DSO

or GMM 852 ■ Ignition Timing 854 ■ Basic Primary Circuit Components 857 ■ Distributor Service 863 ■ Secondary Circuit Tests and Service 863 ■ Case Study 871 ■ Key Terms 871 ■ Summary 871 ■ Review Questions 872 ■ ASE-Style Review Questions 873

CHAPTER 29 Fuel Delivery Systems 874

Objectives 874 ■ Basic Fuel System Diagnosis 875 ■ Guidelines for Safely Working on Fuel Systems 875 ■ Fuel Tanks 876 ■ Filler Caps 879 ■ Fuel Lines and Fittings 881 ■ Fuel Filters 884 ■ Fuel Pumps 886 ■ Case Study 896 ■ Key Terms 896 ■ Summary 896 ■ Review Questions 897 ■ ASE-Style Review Questions 897

CHAPTER 30 Electronic Fuel Injection 899

Objectives 899 ■ Basic EFI 900 ■ Throttle Body Injection (TBI) 905 ■ Port Fuel Injection (PFI) 907 ■ Central Multiport Fuel Injection (CMFI) 912 ■ Gasoline Direct-Injection Systems 913 ■ Light- and Medium-Duty Diesel Fuel Injection 918 ■ Case Study 919 ■ Key Terms 919 ■ Summary 919 ■ Review Questions 920 ■ ASE-Style Review Questions 920

CHAPTER 31 Fuel Injection System Diagnosis and Service 922

Objectives 922 ■ Preliminary Checks 923 ■ Basic EFI System Checks 924 ■ Injector Service 935 ■ Fuel Rail, Injector, and Regulator Service 937 ■ Electronic Throttle Controls 941 ■ Idle Speed Checks 943 ■ Case Study 946 ■ Key Terms 946 ■ Summary 947 ■ Review Questions 947 ■ ASE-Style Review Questions 948

CHAPTER 32 Intake and Exhaust Systems 949

Objectives 949 ■ Vacuum Systems 949 ■ Air Induction System 951 ■ Intake Manifolds 952 ■ Forced Induction Systems 955 ■ Turbochargers 956 ■ Superchargers 962 ■ Exhaust System Components 965 ■ Catalytic Converters 966 ■ Exhaust System Service 970 ■ Case Study 974 ■ Key Terms 974 ■ Summary 974 ■ Review Questions 975 ■ ASE-Style Review Questions 976

CHAPTER 33 Emission Control Systems 978

Objectives 978 ■ Pollutants 978 ■ Emission Control Devices 982 ■ Evaporative Emission Control Systems 985 ■ Precombustion Systems 988 ■ Postcombustion Systems 995 ■ Diesel Emission Controls 1001 ■ Case Study 1006 ■ Key Terms 1006 ■ Summary 1006 ■ Review Questions 1007 ■ ASE-Style Review Questions 1007

CHAPTER 34 Emission Control Diagnosis and Service 1009

Objectives 1009 ■ I/M 240 Test 1009 ■ Testing Emissions 1012 ■ Basic Inspection 1015 ■ Evaporative Emission Control System Diagnosis and Service 1018 ■ PCV System Diagnosis and Service 1023 ■ EGR

System Diagnosis and Service 1025 ■ Catalytic Converter Diagnosis 1032 ■ Air System Diagnosis and Service 1034 ■ Case Study 1037 ■ Key Terms 1037 ■ Summary 1037 ■ Review Questions 1038 ■ ASE-Style Review Questions 1038

CHAPTER 35 Fuels and Other Energy Sources 1040

Objectives 1040 ■ Crude Oil 1040 ■ Gasoline 1043 ■ Basic Gasoline Additives 1044 ■ Oxygenates 1045 ■ Gasoline Quality Testing 1046 ■ Alternatives to Gasoline 1047 ■ Diesel Fuel 1051 ■ Electric Vehicles 1053 ■ Hybrid Electric Vehicles 1054 ■ Fuel Cell Electric Vehicles 1062 ■ Case Study 1067 ■ Key Terms 1067 ■ Summary 1068 ■ Review Questions 1069 ■ ASE-Style Review Questions 1069

SECTION 5 MANUAL TRANSMISSIONS AND TRANSAXLES 1071

CHAPTER 36 Clutches 1071

Objectives 1071 ■ Operation 1071 ■ Clutch Service Safety Precautions 1079 ■ Clutch Maintenance 1079 ■ Clutch Problem Diagnosis 1080 ■ Clutch

Service 1084 ■ Key Terms 1088 ■ Case Study 1089 ■ Summary 1089 ■ Review Questions 1090 ■ ASE-Style Review Questions 1090

CHAPTER 37 Manual Transmissions and Transaxles 1092

Objectives 1092 ■ Transmission Versus Transaxle 1092 ■ Gears 1096 ■ Basic Gear Theory 1097 ■ Transmission/Transaxle Design 1099 ■ Synchronizers 1101 ■ Gearshift Mechanisms 1103 ■ Transmission Power Flow 1104 ■ Transaxle Power Flows 1108 ■ Final Drive Gears and Overall Ratios 1112 ■ Electrical Systems 1112 ■ Case Study 1113 ■ Key Terms 1113 ■ Summary 1113 ■ Review Questions 1114 ■ ASE-Style Review Questions 1115

CHAPTER 38 Manual Transmission/Transaxle Service 1116

Objectives 1116 ■ Lubricant Check 1116 ■ In-Vehicle Service 1118 ■ Diagnosing Problems 1119 ■ Transmission/Transaxle Removal 1124 ■ Cleaning and Inspection 1125 ■ Disassembly and Reassembly of the Differential Case 1131 ■ Reassembly/Reinstallation of Transmission/Transaxle 1134 ■ Case Study 1135 ■ Key Terms 1135 ■ Summary 1135 ■ Review Questions 1136 ■ ASE-Style Review Questions 1136

CHAPTER 39 Drive Axles and Differentials 1138

Objectives 1138 ■ Front-Wheel-Drive (FWD) Axles 1138 ■ Types of CV Joints 1139 ■ Front-Wheel-Drive Applications 1140 ■ CV Joint Service 1142 ■ Rear-Wheel Drive Shafts 1147 ■ Operation of U-Joints 1149 ■ Types of U-Joints 1151 ■ Diagnosis of Drive Shaft and U-Joint Problems 1152 ■ Differentials and Drive Axles 1153 ■ Limited-Slip Differentials 1160 ■ Axle Shafts 1161 ■ Servicing the Final Drive Assembly 1164 ■ Diagnosing Differential Noises 1169 ■ Case Study 1170 ■ Key Terms 1170 ■ Summary 1170 ■ Review Questions 1171 ■ ASE-Style Review Questions 1172

SECTION 6 AUTOMATIC TRANSMISSIONS AND TRANSAXLES 1173

CHAPTER 40 Automatic Transmissions and Transaxles 1173

Objectives 1173 ■ Torque Converter 1174 ■ Lockup Torque

Converter 1178 ■ Planetary Gears 1178 ■ Compound Planetary Gear Sets 1181 ■ Honda's Nonplanetary-Based Transmission 1186 ■ Continuously Variable Transmissions (CVT) 1186 ■ Planetary Gear Controls 1189 ■ Transmission Clutches 1191 ■ Bearings, Bushings, and Thrust Washers 1193 ■ Snaprings 1195 ■ Gaskets and Seals 1196 ■ Final Drives and Differentials 1199 ■ Hydraulic System 1199

- Application of Hydraulics in Transmissions 1200
- Pressure Boosts 1204 ■ Shift Quality 1204
- Hydraulic Circuits 1205 ■ Case Study 1212 ■ Key Terms 1212 ■ Summary 1212 ■ Review Questions 1213
- ASE-Style Review Questions 1214

CHAPTER 41 Electronic Automatic Transmissions 1216

- Objectives 1216 ■ Transmission Control Module 1217
- Hybrid Transmissions 1228 ■ Basic EAT Testing 1232
- Converter Clutch Control Diagnostics 1236 ■ Detailed Testing of Inputs 1238 ■ Detailed Testing of Actuators 1240 ■ Case Study 1241 ■ Key Terms 1242
- Summary 1242 ■ Review Questions 1243
- ASE-Style Review Questions 1244

CHAPTER 42 Automatic Transmission and Transaxle Service 1245

- Objectives 1245 ■ Identification 1245 ■ Basic Diagnostics 1245 ■ Fluid Leaks 1250 ■ Road Testing

- the Vehicle 1252 ■ Checking the Torque Converter 1253
- Diagnosing Hydraulic and Vacuum Control Systems 1256
- Common Problems 1259 ■ Linkages 1260 ■ Case Study 1268 ■ Key Terms 1269 ■ Summary 1269
- Review Questions 1269 ■ ASE-Style Review Questions 1270

CHAPTER 43 Four- and All-Wheel Drive 1271

- Objectives 1271 ■ Types of Four-Wheel Drives 1271
- Four-Wheel-Drive Systems 1274 ■ Transfer Case 1277
- Interaxle Differentials 1277 ■ Locking Hubs 1282
- Four-Wheel-Drive Passenger Cars 1282 ■ All-Wheel-Drive Systems 1284 ■ Diagnosing 4WD and AWD Systems 1284 ■ Servicing 4WD Vehicles 1288 ■ Case Study 1294 ■ Key Terms 1294 ■ Summary 1294
- Review Questions 1294 ■ ASE-Style Review Questions 1295

SECTION 7 SUSPENSION AND STEERING SYSTEMS 1297

CHAPTER 44 Tires and Wheels 1297

- Objectives 1297 ■ Wheels 1297
- Tires 1298 ■ Tire Ratings and Designations 1303 ■ Tire/Wheel Runout 1309 ■ Tire Replacement 1310 ■ Tire Repair 1311 ■ Installation of Tire/Wheel Assembly on the Vehicle 1314 ■ Tire/Wheel Assembly Service 1315 ■ Wheel Bearings 1316 ■ Case Study 1320 ■ Key Terms 1320 ■ Summary 1320
- Review Questions 1321 ■ ASE-Style Review Questions 1322

CHAPTER 45 Suspension Systems 1323

- Objectives 1323 ■ Frames 1323 ■ Suspension System Components 1324 ■ MacPherson Strut Suspension Components 1331 ■ Independent Front Suspension 1334 ■ Basic Front-Suspension Diagnosis 1337 ■ Front-Suspension Component Servicing 1339 ■ Rear-Suspension Systems 1345
- Semi-Independent Suspension 1348 ■ Electronically Controlled Suspensions 1351 ■ Servicing Electronic Suspension Components 1355 ■ Active Suspensions 1357

- Case Study 1359 ■ Key Terms 1359 ■ Summary 1359
- Review Questions 1360 ■ ASE-Style Review Questions 1361

CHAPTER 46 Steering Systems 1363

- Objectives 1363 ■ Manual-Steering Systems 1363
- Power-Steering Systems 1370 ■ Electronically Controlled Power-Steering Systems 1375 ■ Steering System Diagnosis 1378 ■ Diagnosis 1379 ■ Specific Checks 1382 ■ Steering System Servicing 1388
- Power-Steering System Servicing 1390 ■ Four-Wheel Steering Systems 1393 ■ Case Study 1398 ■ Key Terms 1398 ■ Summary 1398 ■ Review Questions 1399
- ASE-Style Review Questions 1400

CHAPTER 47 Wheel Alignment 1402

- Objectives 1402 ■ Alignment Geometry 1403
- Prealignment Inspection 1407 ■ Wheel Alignment Equipment 1409 ■ Alignment Machines 1410
- Performing an Alignment 1411 ■ Four-Wheel-Drive Vehicle Alignment 1421 ■ Case Study 1421
- Key Terms 1421 ■ Summary 1422 ■ Review Questions 1422 ■ ASE-Style Review Questions 1422

SECTION 8 BRAKES**1424****CHAPTER 48 Brake Systems 1424**

Objectives 1424 ■ Friction 1424
 ■ Principles of Hydraulic Brake Systems 1427 ■ Hydraulic Brake System Components 1429
 ■ Master Cylinders 1430 ■ Master

Cylinder Operation 1433 ■ Hydraulic Tubes and Hoses 1435 ■ Hydraulic System Safety Switches and Valves 1437 ■ Drum and Disc Brake Assemblies 1440
 ■ Hydraulic System Service 1442 ■ Power Brakes 1449
 ■ Pushrod Adjustment 1450 ■ Hydraulic Brake Boosters 1451 ■ Electric Parking Brakes 1453 ■ Case Study 1454 ■ Key Terms 1454 ■ Summary 1454
 ■ Review Questions 1455 ■ ASE-Style Review Questions 1456

CHAPTER 49 Drum Brakes 1457

Objectives 1457 ■ Drum Brake Operation 1457
 ■ Drum Brake Components 1458 ■ Drum Brake Designs 1460 ■ Road Testing Brakes 1464 ■ Drum Brake Inspection 1464 ■ Brake Shoes and Linings 1472
 ■ Wheel Cylinder Inspection and Servicing 1475
 ■ Drum Parking Brakes 1475 ■ Case Study 1477
 ■ Key Terms 1478 ■ Summary 1478 ■ Review Questions 1478 ■ ASE-Style Review Questions 1479

CHAPTER 50 Disc Brakes 1481

Objectives 1481 ■ Disc Brake Components and Their Functions 1481 ■ Rear-Wheel Disc Brakes 1486 ■ Disc Brake Diagnosis 1488 ■ Service Guidelines 1490 ■ General Caliper Inspection and Servicing 1491 ■ Rear Disc Brake Calipers 1498
 ■ Rotor Inspection 1499 ■ Rotor Service 1501 ■ Case Study 1503 ■ Key Terms 1503 ■ Summary 1503
 ■ Review Questions 1504 ■ ASE-Style Review Questions 1504

CHAPTER 51 Antilock Brake, Traction Control, and Stability Control Systems 1506

Objectives 1506 ■ Antilock Brakes 1506 ■ ABS Components 1507 ■ Types of Antilock Brake Systems 1511 ■ ABS Operation 1512 ■ Automatic Traction Control 1519 ■ Automatic Stability Control 1521 ■ Antilock Brake System Service 1523
 ■ Diagnosis and Testing 1524 ■ Testing Traction and Stability Control Systems 1530 ■ New Trends 1531
 ■ Case Study 1532 ■ Key Terms 1532 ■ Summary 1532
 ■ Review Questions 1533 ■ ASE-Style Review Questions 1533

SECTION 9 PASSENGER COMFORT**1535****CHAPTER 52 Heating and Air-Conditioning 1535**

Objectives 1535 ■ Ventilation System 1535 ■ Automotive Heating Systems 1536 ■ Heating System Service 1539 ■ Theory of

Automotive Air-Conditioning 1541 ■ Refrigerants 1542

PREFACE

ABOUT THE BOOK

All of the changes to the various systems of an automobile and the integration of those systems have made becoming a successful technician more challenging than ever before. This book, *Automotive Technology: A Systems Approach*, was designed and written to prepare students for those challenges. With students having so much to learn in a short time, why fill the pages of a textbook with information they do not need? The emphasis of this book is on those things that students need to know about the vehicles of yesterday, today, and tomorrow.

This does not mean that the pages are filled with fact after fact. Rather, each topic is explained in a logical way, slowly but surely. After many years of teaching, I have a good sense of how students read and study technical material. I also know what things draw their interest into a topic and keep it there. These things have been incorporated in the writing and features of the book.

This new edition of *Automotive Technology: A Systems Approach* represents the many changes that have taken place in the automotive industry over the past few years. With each new edition, a new challenge (for me) presents itself. What should I include and what should I delete? I hope that I made the right choices. Of course, if I did, I give much of the credit to the feedback I have received from users of the fourth edition and those individuals who reviewed this new edition while it was in the making. They all did a fantastic job and showed that they are truly dedicated to automotive education.

NEW TO THIS EDITION

This new edition is not the previous edition with a new cover and some new chapters. Although much of the information from the fourth edition was retained, each chapter has been updated in response to the changing industry. In addition, there are some new chapters that should be helpful to students and their instructors.

The first section of chapters, which give an overview of the automotive industry, careers, working as a technician, tools, diagnostic equipment, and basic automotive systems, has a totally new look. In fact, the content of these chapters has been rearranged to better match the responsibilities and career of automotive technicians. Chapter 1 explores the career opportunities in the automotive industry. This discussion has been expanded to include more about alternative careers, including the parts distribution world. Chapter 2 covers workplace skills and the ways to go about seeking and selecting a job in the automotive field. This chapter goes through the process of getting a job and keeping it. It also covers some of the duties common to all automotive technicians.

Chapter 3 covers the basic systems of the automobile in a very basic approach and has been updated to include hybrid vehicles. Chapters 4 through 6 cover very important issues regarding hand tools, shop equipment, and safety issues (including bloodborne pathogens). Throughout these chapters, there is a strong emphasis on safely working on today's vehicles and the correct tools required to do so. Chapter 5 gives a brief look at the special and diagnostic tools required for working in each of the eight primary ASE certification areas. The tools discussed include all of the required tools for each area as defined by NATEF.

Chapter 7 is new. It goes through the procedures involved in common safety inspections and preventive maintenance programs. These are the things that students ought to know before they enter into an entry-level position as a technician.

Chapter 8 has been refined and covers the science and math principles that are the basis for the operating principles of an automobile. Too often, we as instructors assume that our students know these basics. I have included this chapter to serve as a reference for those students who want to be good technicians, and to do that they need a better understanding of why things happen the way they do. The rest of Section 1 has been updated with more coverage of

current trends, safety shop equipment, and preventive maintenance services.

Section 2, which includes the chapters on engines, has been changed to include more coverage on the latest engine designs and technologies. There is more coverage on the theory, diagnosis, and service to alloy engines and overhead camshaft engines. There are also discussions on the latest trends, including variable valve timing and lift and variable compression ratios. An emphasis on light-duty diesel engines and those engines used in hybrid vehicles is also part of the entire section.

It seems that everyone appreciated the coverage of basic electricity and electronics in the previous edition. As a result, nothing was deleted from those chapters. However, the organization of the chapters is different. I moved the coverage of electronics and electronic-related equipment later in the section. Hopefully this will allow students to gain a solid understanding of basic electricity before moving on to electronics. Each of the chapters in Section 3 covers the parts and pieces that are part of the latest hybrid systems. I feel that it is better to talk about them as the main topic appears rather than to treat them as something special. For example, although lead-acid batteries are the norm for conventional vehicles, the discussion on batteries includes the various types of batteries used in hybrids. This discussion includes the operation of batteries and fuel cells that may be used in the future. This approach was also used in the discussion of motors and charging systems.

Coverage of all the major electrical systems has been increased to include new technologies. This includes high-voltage systems, new exterior lighting systems, new restraint systems, adaptive systems (such as cruise control), and many new accessories. The rest of the section has been brought up to date with additional coverage on body computers and the use of lab scopes and graphing meters.

The entire Engine Performance section (Section 4) has been updated. New to this edition are introductory chapters that deal with overall engine performance theories and testing. This change represents the approach taken by most experienced technicians. It is hoped that students will be able to grasp a global look at these systems and can become better diagnosticians. The revision of the section covers the individual engine performance systems, their operation, and how to test them with current diagnostic equipment. Added emphasis on diagnostics was the main goal of the revision of the rest of this section.

Sections 5 and 6 cover transmissions and drive-lines. All of the chapters in these sections have been updated to include more coverage on electronic con-

trols. A new chapter (Chapter 41) has been added to the automatic transmission section. This chapter is all about electronically controlled transmissions, which are the standard transmissions of today's vehicles. There is also more coverage on six-, seven-, and eight-speed transmissions, automatic manual transmissions, new differential designs, and electronic automatic transmissions and transaxles. In addition, there is complete coverage on the transmissions used in today's hybrid vehicles.

The suspension and steering systems section has increased coverage on electronic controls and systems. This includes the new magneto-rheological shock absorbers and four-wheel steering systems. Chapter 47, Wheel Alignment, has been updated to include the latest techniques for performing a four-wheel alignment.

The Brakes section has also been updated to reflect current technology. This includes the latest antilock brake, stability control, and traction control systems.

Heating and air-conditioning systems are covered in Section 9. The content in Chapters 52 and 53 was totally revised and include hybrid systems as well as future systems using CO₂ as a refrigerant.

ORGANIZATION AND GOALS OF THIS EDITION

This edition is still a comprehensive guide to the service and repair of our contemporary automobiles. It is still divided into nine sections that relate to the specific automotive systems. The chapters within each section describe the various subsystems and individual components. Diagnostic and service procedures that are unique to different automobile manufacturers also are included in these chapters. Because many automotive systems are integrated, the chapters explain these important relationships in great detail.

Effective diagnostic skills begin with learning to isolate the problem. The exact cause is easier to pinpoint by identifying the system that contains the problem. Learning to think logically about troubleshooting problems is crucial to mastering this essential skill. Therefore, logical troubleshooting techniques are discussed throughout this text. Each chapter describes ways to isolate the problem system and then the individual components of that system.

This *systems approach* gives the student important preparation opportunities for the ASE certification exams. These exams are categorized by the automobile's major systems. The book's sections are outlined to match the ASE test specifications and competency task lists. The review questions at the end of every chapter give students practice in answering ASE-style review questions.

More importantly, a *systems approach* allows students to have a better understanding of the total vehicle. With this understanding, they have a good chance

for a successful career as an automotive technician. That is the single most important goal of this text.

ACKNOWLEDGMENTS

I would like to acknowledge and thank the following dedicated and knowledgeable educators for their

ABOUT THE AUTHOR

Jack Erjavec has become a fixture in the automotive textbook publishing world. He has many years of experience as a technician, educator, author, and editor and has authored or coauthored more than thirty automotive textbooks and training manuals. Mr. Erjavec holds a Master of Arts degree in Vocational and Technical Education from Ohio State University. He spent 20 years at Columbus State

Community College as an instructor and administrator and has also been a long-time affiliate of the North American Council of Automotive Teachers, including serving on the board of directors and as executive vice-president. Jack is also associated with ATMC, SAE, ASA, ATRA, AERA, and other automotive professional associations.

FEATURES OF THE TEXT

Learning how to maintain and repair today's automobiles can be a daunting endeavor. To guide the readers through this complex material, we have built in a series of features that will ease the teaching and learning processes.

OBJECTIVES

Each chapter begins with the purpose of the chapter, stated in a list of objectives. Both cognitive and performance objectives are included in the lists. The objectives state the expected outcome that will result from completing a thorough study of the contents in the chapters.

CAUTIONS AND WARNINGS

Instructors often tell us that shop safety is their most important concern. Cautions and warnings appear frequently in every chapter to alert students to important safety concerns.

SHOP TALK

These features are sprinkled throughout each chapter to give practical, common-sense advice on service and maintenance procedures.

CUSTOMER CARE

Creating a professional image is an important part of shaping a successful career in automotive technology. The customer care tips were written to encourage professional integrity. They give advice on educating customers and keeping them satisfied.

USING SERVICE INFORMATION

Learning to use available service information is critical to becoming a successful technician. The source of information varies from printed material to online materials. The gathering of information can be a time-consuming task but nonetheless is extremely important. We have included a feature that points the student in the right direction to find the right information.

PERFORMANCE TIPS

This feature introduces students to the ideas and theories behind many performance-enhancing techniques used by professionals.

"GO TO" FEATURE

This new feature is used throughout the chapters and tells the student where to go for prerequisite and additional information on the topic.

PHOTO SEQUENCES

Step-by-step photo sequences illustrate practical shop techniques. The photo sequence focus on techniques that are common, need-to-know service and maintenance procedures. These photo sequences give students a clean, detailed image of what to look for when they perform these procedures. This was a popular feature of the previous editions, so we now have a total of 53.

HYBRID VEHICLES

Abundant content on hybrid vehicles and related technologies is presented throughout the textbook within the specific system areas that are being discussed.

PROCEDURES

This feature gives detailed, step-by-step instructions for important service and maintenance procedures. These hands-on procedures appear frequently and are given in great detail because they help to develop good shop skills and help to meet competencies required for ASE certification.

CASE STUDIES

Case studies highlight our emphasis on logical troubleshooting. A service problem is outlined at the end of the chapters, and then a technician's solution is described. This gives the student a practical example of logical troubleshooting.

KEY TERMS

Each chapter ends with a list of the terms that were introduced in the chapter. These terms are highlighted in the text when they are first used, and many are defined in the glossary.

SUMMARY

Highlights and key bits of information from the chapter are listed at the end of each chapter. This listing is designed to serve as a refresher for the reader.

REVIEW QUESTIONS

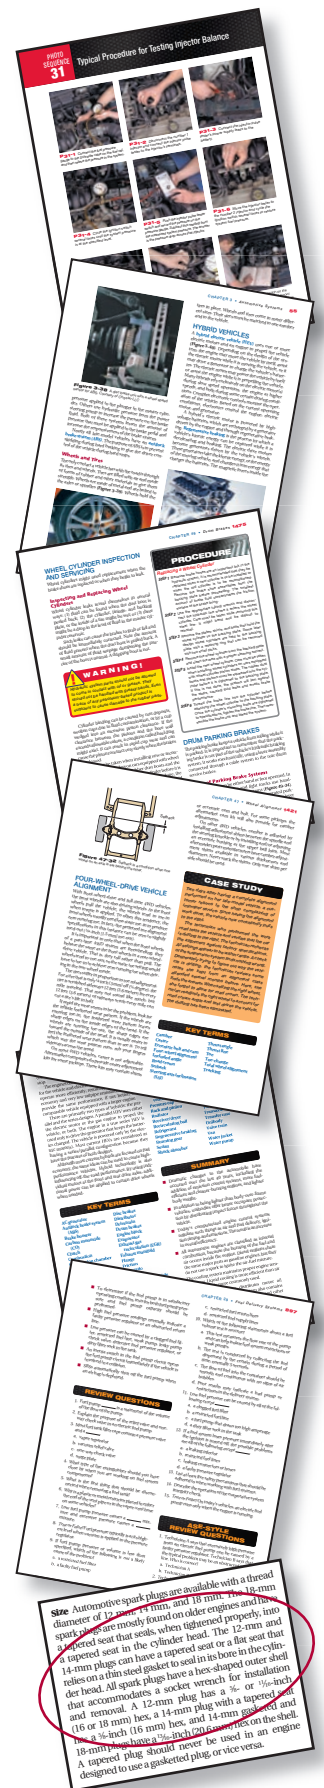

A combination of short-answer essay, fill-in-the-blank, and multiple-choice, questions make up the end-of-chapter review questions. Different question types are used to challenge the reader's understanding of the chapter's contents. The chapter objectives are used as the basis for the review questions.

ASE-STYLE REVIEW QUESTIONS

In any chapter that relates to one of the ASE certification areas, there are ten ASE-style review questions that relate to that area. Some are quite challenging and others are a simple review of the contents of the chapter.

METRIC EQUIVALENTS

Throughout the text, all measurements are given in UCS and metric increments.

SUPPLEMENTS

The *Automotive Technology* package offers a full complement of supplements.

Student Online Companion

Each textbook provides access to the new *Student Online Companion*, which includes the following components:

- **PowerPoint**—Study outlines with images for each textbook chapter.
- **ASE-Style Practice Questions**—Over 350 questions to help students review chapter material and get familiar with the question types they will see on certification exams.
- **Web Links and Activities**—Links to industry Web resources/reference material with related research activities for many.
- **Challenging Concepts**—45 videos, narration, and questions to help students comprehend more challenging topics.
- **Interactive Online Game**—A self-review Q&A game to help students comprehend the chapter material.

Tech Manual

The *Tech Manual* (ISBN 1428311505) offers students opportunities to strengthen their comprehension of key concepts and to develop their hands-on, practical shop experience. Each chapter includes Concept Activities and Job Sheets, many of which are directly correlated to specific NATEF tasks. Service manual report sheets, case studies, and review questions also are included to offer a rounded approach to each lesson.

Instructor Resources

The *Instructor Resources* DVD (ISBN 1428311521) for the fifth edition includes the following components to help minimize instructor prep time and engage students:

- **PowerPoint**—Chapter outlines with images, animations, and video clips for each textbook chapter.
- **Computerized Test Bank in Exam View**—Hundreds of modifiable questions for exams, quizzes, in-class work, or homework assignments. All applicable questions are correlated to the 2008 NATEF Automobile Standards.
- **Image Library**—A searchable database of hundreds of images from the textbook that can be used to easily customize the PowerPoint outlines.
- **Challenging Concepts**—45 videos, narration, and questions help students comprehend more challenging topics.
- **End-of-Chapter Review Questions**—Word files of all textbook review questions are provided on the DVD.
- **Instructor's Manual**—An electronic version of the Instructor's Manual is included in the Instructor Resources.
- **NATEF Correlations**—The 2008 NATEF Automobile Standards are correlated to the chapter and page numbers of the core text.
- **Job Sheet Template**—For instructors who develop their own job sheets, a template is provided to help with their formatting.

Instructor's Manual

This comprehensive guide provides lecture outlines with teaching hints, answers to review questions from the textbook, and answers to *Tech Manual* questions, as well as guidelines for using the *Tech Manual*. A correlation chart to the 2008 NATEF Task List provides references to topic coverage in both the text and *Tech Manual*.

CAREERS IN THE AUTOMOTIVE INDUSTRY

OBJECTIVES

■ Describe the reasons why today's automotive industry is considered a global industry. ■ Explain how computer technology has changed the way vehicles are built and serviced. ■ Explain why the need for qualified automotive technicians is increasing. ■ Describe the major types of businesses that employ automotive technicians. ■ List some of the many job opportunities available to people with a background in automotive technology. ■ Describe the different ways a student can gain work experience while attending classes. ■ Describe the requirements for ASE certification as an automotive technician and as a master auto technician.

THE AUTOMOTIVE INDUSTRY

Each year millions of new cars and light trucks are produced and sold in North America (**Figure 1-1**). The automotive industry's part in the total economy of the United States is second only to the food industry. Manufacturing, selling, and servicing these vehicles are parts of an incredibly large, diverse, and expanding industry.

Figure 1-1 Ford's F-150 pickup has been the best selling vehicle in America for many years.

Thirty years ago, America's "big three" automakers—General Motors Corporation, Ford Motor Company, and Chrysler Corporation—dominated the auto industry. This is no longer true. The industry is now a global industry (**Table 1-1**). Automakers from Japan, Korea, Germany, Sweden, and other European and Asian countries compete with companies in the United States for domestic and foreign sales.

Several foreign manufacturers, such as Honda, Toyota, and BMW, operate assembly plants in the United States and Canada. Automobile manufacturers have joined together, or merged, to reduce costs and increase market share. In addition, many smaller auto manufacturers have been bought by larger companies to form larger global automobile companies. Most often the ownership of a company is not readily identifiable by the brand name. An example of this is Ford Motor Company; Ford brands include Ford, Mercury, Lincoln, Volvo, and Mazda.

There are also a number of vehicles built jointly by the United States and foreign manufacturers. These vehicles are built and sold in North America or exported to other countries.

TABLE 1-1 WORLDWIDE UNIT SALES OF PASSENGER CARS, LIGHT-, MEDIUM-, AND HEAVY-DUTY TRUCKS

Manufacturer	Country of Origin	Approx. Units Sold Annually	Notes
Toyota Motor Corp.	Japan	8.8 million	Includes Lexus, Scion, Daihatsu, and Hino
General Motors	U.S.	8.7 million	Includes GM/Daewoo, Holden, Hummer, Opel, and Saab
Ford Motor Co.	U.S.	6.0 million	Includes Volvo Car Corp.
Volkswagen AG	Germany	5.7 million	Includes Audi, Bentley, Bugatti, Lamborghini, Skoda, and Seat
Hyundai-Kia Automotive	Korea	3.8 million	Includes Hyundai and Kia
Honda Motor Co.	Japan	3.6 million	Includes Acura
Nissan Motor Co.	Japan	3.5 million	Includes Infiniti
PSA/Peugeot-Citroen SA	France	3.4 million	Includes Citroen and Peugeot
Daimler Benz AG	Germany	2.7 million	Includes Mercedes-Benz, Smart, EvoBus, Freightliner, and Mitsubishi Fuso
Renault SA	France	2.4 million	Includes Dacia and Renault-Samsung Motors
Fiat S.p.A.	Italy	2.3 million	Includes Ferrari, Alfa Romeo, Iveco, Lancia, and Maserati
Suzuki Motor Corp.	Japan	2.2 million	
Chrysler LLC	U.S.	2.0 million	
BMW Group 11	Germany	1.4 million	Includes Rolls-Royce and Cooper
Mitsubishi Motors Corp.	Japan	1.3 million	
Mazda Motor Corp.	Japan	1.2 million	
AutoVaz	Russia	860 thousand	
China FAW Group Corp.	China	682 thousand	
Isuzu Motors Ltd.	Japan	651 thousand	
Fuji Heavy Industries Ltd.	Japan	602 thousand	Includes Subaru
Dongfeng Motor Corp.	China	460 thousand	
Chongqing Changan	China	456 thousand	
Tata Motors Ltd.	India	454 thousand	Includes Jaguar and Land Rover
Shanghai Automotive	China	420 thousand	Includes Wuling
Beijing Automobile Works	China	337 thousand	
Chery Automobile Co.	China	304 thousand	
Hafei Motor Co.	China	231 thousand	
Volvo Truck Group	Sweden	230 thousand	Includes Mack Trucks, RVI, Volvo Buses, and Nissan Diesel Motor Co.
AutoGaz	Russia	224 thousand	
Zhejiang Geely	China	204 thousand	
Anhui Jianghuai	China	172 thousand	
Paccar	U.S.	167 thousand	Includes DAF, Kenworth, Leyland, Peterbilt, and Foden
Navistar International	U.S.	158 thousand	

TABLE 1-1 *Continued*

Manufacturer	Country of Origin	Approx. Units Sold Annually	Notes
Mahindra & Mahindra	India	148 thousand	
Iran Khodro	Iran	132 thousand	
Proton	Malaysia	126 thousand	Includes Lotus
Shenyang Brilliance Jinbei	China	126 thousand	
SsangYong Motor Co.	Korea	110 thousand	
Porsche AG	Germany	96 thousand	
Jiangxi Changhe	China	89 thousand	
MAN Nutzfahrzeuge	Germany	87 thousand	
Scania	Sweden	65 thousand	
MG Rover Group	U.K.	53 thousand	
Others	China	122 thousand	Includes Great Wall Motor Co. and Southeast (Fujian) Motor Co.
Others	India	116 thousand	Includes Ashok Leyland, Eicher Motors, Force Motors/Bajaj Tempo, and Hindustan Motors Ltd

This cooperation between manufacturers has given customers an extremely wide selection of vehicles to choose from. This variety has also created new challenges for automotive technicians, based on one simple fact: Along with the different models come different systems.

The Importance of Auto Technicians

The automobile started out as a simple mechanical beast. It moved people and things with little regard to the environment, safety, and comfort. Through the years these concerns have provided the impetus for design changes. One area that has affected automobile design the most is the same area that has greatly influenced the rest of our lives, electronics. Today's automobiles are sophisticated electronically controlled machines. To provide comfort and safety while being friendly to the environment, today's automobiles use the latest developments of many different technologies—mechanical and chemical engineering, hydraulics, refrigeration, pneumatics, physics, and, of course, electronics.

An understanding of electronics is a must for all automotive technicians (**Figure 1-2**). The needed level of understanding is not that of an engineer; rather, technicians need a practical understanding of electronics. In addition to having the mechanical skills needed to remove, repair, and replace faulty or damaged components, today's technician

Figure 1-2 An understanding of electronics is a must for all automotive technicians.

also must be able to diagnose and service complex electronic systems.

Computers and electronic devices are used to control the operation of an engine. Because of these controls, today's automobiles use less fuel, perform

Figure 1-3 The Toyota Prius is the best selling hybrid vehicle. *Courtesy of Dewhurst Photography and Toyota Motor Sales, U.S.A., Inc.*

better, and run cleaner than those in the past. Electronic controls also are used in nearly all systems of an automobile. The number of electronically controlled systems on cars and trucks increases each year. There are many reasons for the heavy insurge of electronics into automobiles. Electronics are based on electricity and electricity moves at the speed of light. This means the operation of the various systems can be monitored and changed very quickly. Electronic components have no moving parts, are durable, do not require periodic adjustments, and are very light. All of these allow today's automobiles to be more efficient, cleaner, safer, and better performing than vehicles of the past.

The application of electronics has also led to the success of hybrid vehicles (**Figure 1-3**). A hybrid vehicle has two separate sources of power. Those power sources can work together to move the vehicle or can power the vehicle on their own. Today's hybrid vehicles are moved by electric motors and/or a gasoline engine. Hybrid vehicles are complex machines and all who work on them must be properly trained.

The design of today's automobiles is also influenced by legislation. Throughout history, automobile manufacturers have been required to respond to new laws designed to make automobiles safer and cleaner-running. In response to these laws, new systems and components are introduced. Anyone desiring to be a good technician must regularly update his or her skills to keep up with the technology.

Legislation has not only influenced the design of gasoline-powered vehicles, it has also led to a wider use of diesel engines in passenger vehicles. By mandating cleaner diesel fuels, the laws have opened the door for clean burning and highly efficient diesel engines. These new engines are also fit with electronic controls.

Figure 1-4 Good technicians are able to follow specific manufacturers' diagnostic charts and interpret the results of diagnostic tests.

Many states have laws that require owners to have their vehicles' exhaust tested on an annual basis. Some states require automobiles to pass an annual or biannual **Inspection/Maintenance (I/M)** test. Today's automotive technician must be able to find the cause of test failures and correct them.

The Need for Quality Service

The need for good technicians continues to grow. Currently there is a great shortage of qualified automotive technicians. This means there are, and will be, excellent career opportunities for good technicians. Good technicians are able to diagnose and repair problems in today's automobiles (**Figure 1-4**).

Car owners demand that when things go wrong, they should be "fixed right the first time." The primary reason some technicians are unable to fix a particular problem is simply that they cannot find the cause of the problem. Today's vehicles are complex and a great amount of knowledge and understanding is required to diagnose them. Today's technicians must have good **diagnostic skills**. Technicians who can identify and solve problems the first time the vehicle is brought into the shop are wanted by the industry and have many excellent career opportunities.

The Need for Ongoing Service

Electronic controls have not eliminated the need for routine service and scheduled maintenance (**Figure 1-5**). In fact, they have made it more important than ever. Although electronic systems can make adjustments to compensate for some problems, a computer cannot replace worn parts. A computer

Figure 1-5 Regular preventive maintenance (PM) is important for keeping electronic control systems operating correctly. A common part of PM is changing the engine's oil and filter.

cannot tighten loose belts or change dirty coolant or engine oil. Simple problems such as these can set off a chain of unwanted events in an engine control system. Electronic controls are designed to help a well-maintained vehicle operate efficiently. They are not designed to repair systems.

Electronic systems are based on the same principles as a computer. In fact, these systems rely on a computer to control the operation of a component or system. Instead of a keyboard, automotive electronic systems rely on sensors or inputs. These send information to the computer. The computer receives the inputs and through computer logic causes a component to change the way it is operating. These controlled outputs are similar to your computer screen or printer.

Each automobile manufacturer recommends that certain maintenance services be performed according to a specific schedule. These maintenance procedures are referred to as **preventive maintenance (PM)** because they are designed to prevent problems. Scheduled PM normally includes oil and filter changes; coolant and lubrication services; replacement of belts and hoses; and replacement of spark plugs, filters, and worn electrical parts (**Figure 1-6**).

If the owner fails to follow the recommended maintenance schedule, the vehicle's warranty might not cover problems that result. For example, if the engine fails during the period covered by the warranty, the warranty may not cover the engine if the owner does not have proof that the engine's oil was changed according to the recommended schedule.

Warranties A new car **warranty** is an agreement by the auto manufacturer to have its authorized dealers repair, replace, or adjust certain parts if they become defective. This agreement typically lasts until the vehicle has been driven 36,000 miles (58,000 km), and/or has been owned for 3 years.

The details of most warranties vary with the manufacturer, vehicle model, and year. Most manufacturers also provide a separate warranty for the powertrain (engine, transmission, and so on) that covers these parts for a longer period than the basic warranty. There are also additional warranties for other systems or components of the vehicle.

Often, according to the terms of the warranty the owner must pay a certain amount of money, called the **deductible**. The manufacturer pays for all repair costs over the deductible amount.

Battery and tire warranties are often prorated, which means that the amount of the repair bill covered by the warranty decreases over time. Some warranties are held by a third party, such as the manufacturer of the battery or tires. Although the manufacturer sold the vehicle with the battery or set of tires, their warranty is the manufacturer's responsibility.

There are also two government-mandated warranties: the Federal Emissions Defect Warranty and the Federal Emissions Performance Warranty. The Federal Emissions Defect Warranty ensures that the vehicle meets all required emissions regulations and that the vehicle's emission control system works as designed and will continue to do so for 2 years or 24,000 miles. The warranty does not cover problems caused by accidents, floods, misuse, modifications, poor maintenance, or the use of leaded fuels. The systems typically covered by this warranty are:

- Air induction
- Fuel metering
- Ignition
- Exhaust
- Positive crankcase ventilation
- Fuel evaporative control
- Emission control system sensors

The Federal Emissions Performance Warranty covers the catalytic converter(s) and engine control module for a period of 8 years or 80,000 miles. If the owner properly maintains the vehicle and it fails an emissions test approved by the Environmental Protection Agency (EPA), an authorized service facility will repair or replace the emission-related parts covered by the warranty at no cost to the owner. Some states, such as California, require the manufacturers to offer additional or extended warranties.

5,000 MILES OR 6 MONTHS

- Replace engine oil and oil filter
- Rotate tires
- Visually inspect brake linings

Additional maintenance items for special operating conditions

- Inspect ball joints and dust covers
- Inspect drive shaft boots
- Inspect air filter
- Inspect steering linkage and boots
- Retorque drive shaft bolt
- Tighten nuts and bolts on chassis

10,000 MILES OR 12 MONTHS*(Same as 5,000 miles and 6 months)****Additional maintenance items for special operating conditions****(Same as 5,000 miles and 6 months)***15,000 MILES OR 18 MONTHS***(Same as 5,000 miles and 6 months)**Plus:*

- Clean cabin air filter
- Inspect the following:
 - Ball joints and dust covers
 - Drive shaft boots
 - Engine air filter
 - Steering linkage and boots
 - Retorque drive shaft bolt
 - Tighten nuts and bolts on chassis

20,000 MILES OR 24 MONTHS*(Same as 5,000 miles and 6 months)**Plus:*

- Replace cabin filter

Additional maintenance items for special operating conditions*(Same as 5,000 miles and 6 months)***25,000 MILES OR 30 MONTHS***(Same as 5,000 miles and 6 months)****Additional maintenance items for special operating conditions****(Same as 5,000 miles and 6 months)***30,000 MILES OR 36 MONTHS***(Same as 5,000 miles and 6 months)**Plus:*

- Replace cabin filter
- Rotate tire
- Replace engine air filter
- In addition, inspect the following:
 - Brake lines and hoses
 - Differential oil

- Engine coolant
- Exhaust pipes and mountings
- Fuel lines and connections, fuel tank band, and fuel tank vapor system hoses
- Fuel tank cap gasket
- Radiator core and condenser
- Steering gear box
- Steering linkage and boots
- Transmission fluid or oil

Additional maintenance items for special operating conditions*(Same as 5,000 miles and 6 months)***35,000 MILES OR 42 MONTHS***(Same as 5,000 miles and 6 months)****Additional maintenance items for special operating conditions****(Same as 5,000 miles and 6 months)***40,000 MILES OR 48 MONTHS***(Same as 20,000 miles and 24 months)****Additional maintenance items for special operating conditions****(Same as 20,000 miles and 24 months)***45,000 MILES OR 54 MONTHS***(Same as 15,000 miles and 18 months)****Additional maintenance items for special operating conditions****(Same as 15,000 miles and 18 months)***50,000 MILES OR 60 MONTHS***(Same as 5,000 miles and 6 months)****Additional maintenance items for special operating conditions****(Same as 5,000 miles and 6 months)***55,000 MILES OR 66 MONTHS***(Same as 20,000 miles and 24 months)****Additional maintenance items for special operating conditions****(Same as 20,000 miles and 24 months)***60,000 MILES OR 72 MONTHS***(Same as 15,000 miles and 18 months)**Plus:*

- Inspect:
 - Drive belts
 - Engine valve clearance

Additional maintenance items for special operating conditions*(Same as 15,000 miles and 18 months)**Plus:*

- Replace front differential oil
- Replace transmission oil or fluid

Figure 1-6 A typical preventive maintenance schedule.

Figure 1-7 Automotive service technicians can enjoy careers in many different automotive businesses.

All warranty information can be found in the vehicle's owner's manual. Whenever there are questions about the warranties, carefully read that section in the owner's manual. If you are working on a vehicle and know that the part or system is covered under a warranty, make sure to tell the customer before proceeding with your work. Doing this will save the customer money and you will earn his or her trust.

Career Opportunities

Automotive service technicians can enjoy careers in many different types of automotive businesses (**Figure 1-7**). Because of the skills required to be a qualified technician, there are also career opportunities for those who do not want to repair automobiles the rest of their lives. There are also many opportunities for good technicians who want to change careers. The knowledge required to be a good service technician can open many doors of opportunity.

Dealerships New car dealerships (**Figure 1-8**) serve as the link between the vehicle manufacturer and the customer. They are privately owned businesses. Most dealerships are franchised operations, which means the owners have signed a contract with particular auto manufacturers and have agreed to sell and service their vehicles.

The manufacturer usually sets the sales and service policies of the dealership. Most warranty repair work is done at the dealership. The manufacturer then pays the dealership for making the repair. The manufacturer also provides the service department

at the dealership with the training, special tools, equipment, and information needed to repair its vehicles. The manufacturers also help the dealerships get service business. Often, their commercials stress the importance of using their replacement parts and promote their technicians as the most qualified to work on their products.

Working for a new car dealership can have many advantages. Technical support, equipment, and the opportunity for ongoing training are usually excellent. At a dealership, you have a chance to become very skillful in working on the vehicles you service. However, working on one or two types of vehicles does not appeal to everyone. Some technicians want diversity.

Figure 1-8 Dealerships sell and service vehicles made by specific auto manufacturers.

Figure 1-9 Full-service gasoline stations are not as common as they used to be, but they are a good example of an independent service shop.

Independent Service Shops Independent shops (Figure 1-9) may service all types of vehicles or may specialize in particular types of cars and trucks or specific systems of a car. Independent shops outnumber dealerships by six to one. As the name states, an independent service shop is not associated with any particular automobile manufacturer. Many independent shops are started by technicians eager to be their own boss and run their own business.

An independent shop may range in size from a two-bay garage with two to four technicians to a multiple-bay service center with twenty to thirty technicians. A **bay** is simply a work area for a complete vehicle (Figure 1-10). The amount of equipment in an independent shop varies; however, most are well equipped to do the work they do best. Working in an

Figure 1-10 A bay in an independent service shop.

independent shop may help you develop into a well-rounded technician.

Specialty shops specialize in areas such as engine rebuilding, transmission/transaxle overhauling, and air conditioning, brake, exhaust, cooling, emissions, and electrical work. A popular type of specialty shop is the “quick lube” shop, which takes care of the PM of vehicles. It hires lubrication specialists who change fluids, belts, and hoses in addition to checking certain safety items on the vehicle.

The number of specialty shops that service and repair only one or two systems of the automobile has steadily increased over the past 10 to 20 years. Technicians employed by these shops have the opportunity to become very skillful in one particular area of service.

Franchise Repair Shop A great number of jobs are available at service shops that are run by large companies such as Firestone, Goodyear, and Midas. These shops do not normally service and repair all of the systems of the automobile. However, their customers do come in with a variety of service needs. Technicians employed by these shops have the opportunity to become very proficient in many areas of service and repair.

Some independent shops may look like they are part of a franchise but are actually independent. Good examples of this type of shop are the NAPA service centers (Figure 1-11). These centers are not controlled by NAPA, nor are they franchises of NAPA. They are called NAPA service centers because the facility has met NAPA’s standards of quality and the owner has agreed to use NAPA as the primary source of parts and equipment.

Figure 1-11 NAPA service centers are a good example of an independent repair shop that has affiliated with a large business. In these arrangements, the shops are still run independently.

Store-Associated Shops Other major employers of auto technicians are the service departments of department stores. Many large stores that sell automotive parts often offer certain types of automotive services, such as brake, exhaust system, and wheel and tire work.

Fleet Service and Maintenance Any company that relies on several vehicles to do its business faces an ongoing vehicle service and PM problem. Small fleets often send their vehicles to an independent shop for maintenance and repair. Large fleets, however, usually have their own PM and repair facilities and technicians (**Figure 1-12**).

Utility companies (such as electric, telephone, or cable TV), car rental companies, overnight delivery

services, and taxicab companies are good examples of businesses that usually have their own service departments. These companies normally purchase their vehicles from one manufacturer. Technicians who work on these fleets have the same opportunities and benefits as technicians in a dealership. In fact, the technicians of some large fleets are authorized to do warranty work for the manufacturer. Many good career opportunities are available in this segment of the auto service industry.

JOB CLASSIFICATIONS

The automotive industry offers numerous types of employment for people with a good understanding of automotive systems.

Service Technician

A **service technician** (**Figure 1-13**) assesses vehicle problems, performs all necessary diagnostic tests, and competently repairs or replaces faulty components. The skills to do this job are based on a sound understanding of auto technology, on-the-job experience, and continuous training in new technology as it is introduced by auto manufacturers.

Individuals skilled in automotive service are called technicians, not mechanics. There is a good reason for this. *Mechanic* stresses the ability to repair and service mechanical systems. While this skill is still very much needed, it is only part of the technician's overall job. Today's vehicles require mechanical knowledge plus an understanding of other technologies, such as electronics, hydraulics, and pneumatics.

Figure 1-12 Large fleets usually have their own preventive maintenance and repair facilities and technicians.

Figure 1-13 A service technician troubleshoots problems, performs all necessary diagnostic tests, and competently repairs or replaces faulty components.

Figure 1-14 Specialty technicians work on only one vehicle system, such as brakes.

A technician may work on all systems of the car or may become specialized. Specialty technicians concentrate on servicing one system of the automobile, such as electrical, brakes (**Figure 1-14**), or transmission. These specialties require advanced and continuous training in that particular field.

In many automotive shops, the technician also has the responsibility for diagnosing the concerns of the customer and preparing a cost estimate for the required services.

Often individuals begin their career as a technician in a new car dealership by performing new car preparation, commonly referred to as “new car prep.” The basic purpose of new car prep is to make a vehicle ready to be delivered to a customer. Each dealership has a list of items and services that are performed prior to delivery. Some of the services may include removing the protective plastic from the vehicle’s exterior and interior and installing floor mats. At times, new car prep includes tightening certain bolts that may have been intentionally left loose for shipping. New car prep is a great way for a new technician to become familiar with the vehicles sold at the dealership.

Shop Foreman

The **shop foreman** is the one who helps technicians with more difficult tasks and serves as the quality control expert. In some shops, this is the role of the **lead tech**. For the most part, both jobs are the same. Some shops have technician teams. On these teams, there are several technicians, each with a different level of expertise. The lead tech is sort of the shop foreman of the team. Lead techs and shop foremen have a good deal of experience and excellent diagnostic skills.

Service Advisor

The person who greets customers at a service center is the **service advisor** (**Figure 1-15**), sometimes called a service writer or consultant. Service advisors need to have an understanding of all major systems of an automobile and be able to identify all major

Figure 1-15 A service advisor’s main job is to record the customer’s concerns.

components and their locations. They also must be able to describe the function of each of those components and be able to identify related components. A good understanding of the recommended service and maintenance intervals and procedures is also required. With this knowledge they are able to explain the importance and complexity of each service and are able to recommend other services.

A thorough understanding of warranty policies and procedures is also a must. Service advisors must be able to explain and verify the applicability of warranties, service contracts, service bulletins, and campaign/recalls procedures.

Service advisors also serve as the liaison between the customer and the technician in most dealerships. They have responsibility for explaining the customer's concerns and/or requests to the technician plus keeping track of the progress made by the technician so the customer can be informed. This monitoring is also important because it impacts the completion of service on the vehicles of other customers.

Often automotive technicians or students of automotive service programs realize a need to change career choices but desire to stay in the service industry. Becoming a service writer, advisor, or consultant is a good alternative. This job is good for those who have the technical knowledge but lack the desire or physical abilities to physically work on automobiles.

Many of the requirements for being a successful technician apply to being a successful service consultant. However, being a service consultant requires greater skill levels in customer relations, internal communication and relations, and sales. Service consultants must communicate well with customers, over the telephone or in person, in order to satisfy their needs or concerns. Most often this satisfaction involves the completion of a repair order, which contains customer information, instructions to the technicians, and a cost estimate.

Accurate estimates are not only highly appreciated by the customer, but they are also required by law in most states. Writing an accurate estimate requires a solid understanding of the automobile, good communications with the customers and technicians, and good reading and math skills.

Most shops use computers to generate the repair orders and estimates and to schedule the shop's workload. Therefore, having solid computer skills is an asset for service advisors.

Service Manager

The service manager is responsible for the operation of the entire service department at a large dealership or independent shop. Normally, customer concerns

and complaints are handled by the service manager. Therefore, a good service manager has good people skills in addition to organizational skills and a solid automotive background.

In a dealership, the service manager makes sure the manufacturers' policies on warranties, service procedures, and customer relations are carried out. The service manager also arranges for technician training and keeps all other shop personnel informed and working together.

Service Director

Large new car dealerships often have a **service director** who oversees the operation of the service and parts departments as well as the body shop. The service director has the main responsibility of keeping the three departments profitable. The service director coordinates the activities of these separate departments to ensure efficiency.

Many service directors began their career as technicians. As technicians they demonstrated a solid knowledge of the automotive field and had outstanding customer relations skills and good business sense. The transition from technician to director typically involves promotion to various other managerial positions first.

Parts Counterperson

A parts counterperson (**Figure 1-16**) can have different duties and is commonly called a parts person or specialist. Parts specialists are found in nearly all automotive dealerships and auto parts retail and wholesale stores. They sell auto parts directly to customers and issue materials and supplies to auto repair specialists working in automotive services facilities and body shops. A parts counterperson must be friendly, professional, and efficient when working with all customers, both on the phone and in person.

Figure 1-16 A parts counterperson has an important role in the operation of a store or dealership.

Depending on the parts store or department, duties may also include delivering parts, purchasing a variety of automotive parts, maintaining inventory levels, and issuing parts to customers and technicians. Responsibilities include preparing purchase orders, scheduling deliveries, assisting in the receipt and storage of parts and supplies, and maintaining contact with vendors. An understanding of automotive terminology and systems is a must for good parts counterpersons.

This career is an excellent alternative for those who know about cars but would rather not work on them. Much of the knowledge required to be a technician is also required for a parts person. However, a parts specialist requires a different set of skills. Most automotive parts specialists acquire the sales and customer service skills needed to be successful primarily through on-the-job experience and training. They may also gain the necessary technical knowledge on the job or through educational programs and/or experience. To better understand the world of the parts industry refer to **Figure 1–17**, which defines the common terms used by parts personnel.

Parts Manager

The parts manager is in charge of ordering all replacement parts for the repairs the shop performs. The ordering and timely delivery of parts is extremely important for the smooth operation of the shop. Delays in obtaining parts or omitting a small but crucial part from the initial parts order can cause frustrating holdups for both the service technicians and customers.

Most dealerships and large independent shops keep an inventory of commonly used parts, such as filters, belts, hoses, and gaskets. The parts manager is responsible for maintaining this inventory.

An understanding of automotive systems and their parts, thoroughness, attention to detail, and the ability to work with people face to face and over the phone are essential for a parts manager.

RELATED CAREER OPPORTUNITIES

In addition to careers in automotive service, there are many other job opportunities directly related to the automotive industry.

Parts Distribution

The **aftermarket** refers to the network of businesses (**Figure 1–18**) that supplies replacement parts to independent service shops, car and truck dealerships, fleet operations, and the general public.

Vehicle manufacturers and independent parts manufacturers sell and supply parts to approximately a thousand warehouse distributors throughout the United States. These **warehouse distributors (WDs)** carry substantial inventories of many part lines.

Warehouse distributors serve as large distribution centers. WDs sell and supply parts to parts wholesalers, commonly known as jobbers.

Jobbers sell parts and supplies to shops and do-it-yourselfers. Jobbers often have a delivery service that gets the desired parts to a shop shortly after it ordered them. Some parts stores focus on individual or walk-in customers. These businesses offer the do-it-yourselfers repair advice, and some even offer testing of old components. Selling good parts at a reasonable price and offering extra services to their customers are the characteristics of successful parts stores. Many jobbers operate machine shops that offer another source of employment for skilled technicians. Jobbers or parts stores can be independently owned and operated. They can also be part of a larger national chain (**Figure 1–19**). Auto manufacturers have also set up their own parts distribution systems to their dealerships and authorized service outlets. Parts manufactured by the original vehicle manufacturer are called **original equipment manufacturer (OEM)** parts.

Opportunities for employment exist at all levels in the parts distribution network, from warehouse distributors to the counterpeople at local jobber outlets.

Marketing and Sales

Companies that manufacture equipment and parts for the service industry are constantly searching for knowledgeable people to represent and sell their products. For example, a sales representative working for an aftermarket parts manufacturer should have a good knowledge of the company's products. The sales representative also works with WDs, jobbers, and service shops to make sure the parts are being sold and installed correctly. They also help coordinate training and supply information so that everyone using their products is properly trained and informed.

Other Opportunities

Other career possibilities for those trained in automotive service include automobile and truck recyclers, insurance company claims adjusters, auto body shop technicians, and trainers for the various manufacturers or instructors for an automotive program (**Figure 1–20**). The latter two careers require solid experience and a thorough understanding of the automobile. It is not easy being an instructor or

ACCOUNTS RECEIVABLE Money due from a customer.	NET PRICE A business's profit after deducting the cost of all of its merchandise and all expenses involved in operating the business.
ALPHANUMERIC A numbering system commonly used in parts catalogs and price listings. This system uses a combination of letters and numbers. They are placed in order starting from the left digit and working across to the right.	NO-RETURN POLICY A store policy that certain parts cannot be returned after purchase. It is common to have a no-return policy on electrical and electronic parts.
BACK ORDER Parts ordered from a supplier that have not been shipped to the store or shop because the supplier has none in its inventory.	ON HAND The quantity of an item that the store or shop has in its possession.
BILL OF LADING A shipping document acknowledging receipt of goods and stating terms of delivery.	PERPETUAL INVENTORY A method of keeping a continuous record of stock on hand through sales receipts and/or invoices.
CATALOGING The process of looking up the needed parts in a parts catalog.	PHYSICAL INVENTORY The process whereby each part is manually counted and the number on hand is written on a form or entered into a computer.
CORE CHARGE A charge that is added when a customer buys a remanufactured part. Core charges are refunded to the customer when he or she returns a rebuildable part.	PROFIT The amount received for goods or services above the shop's or store's cost for the part or service.
CORRECTION BULLETIN A bulletin that corrects catalog errors due to printing errors or inaccurately assigned part numbers.	PURCHASE ORDER A form giving someone the authority to purchase goods or services for a company.
CUSTOMER RELATIONS A description of how a salesperson interacts with the customer.	REMANUFACTURED PART A part that has been reconditioned to its original specifications and standards.
DEALERS The jobber's wholesale customers, such as service stations, garages, and vehicle dealers, who install parts in their customers' vehicles.	RESTOCKING FEE The fee charged by a store or supplier for having to handle a returned part.
DISCOUNT The amount of savings being offered to a customer, normally expressed as a percentage.	RETAIL Selling merchandise to walk-in trade (do-it-yourselfers).
DISTRIBUTOR A large-volume parts-stocking business that sells to wholesalers.	RETURN POLICY A policy regarding the return of unwanted and unneeded parts. Return policies may include restocking fees or prohibit the return of certain parts.
FREIGHT CHARGE A charge added to special order parts to cover their transportation to the store.	SELLING PRICE The price at which a part is sold. This price will vary according to the type of customer (retail or wholesale) who is purchasing the part.
GROSS PROFIT The selling price of a part minus its cost.	SPECIAL ORDER An order placed whenever a customer purchases an item not normally kept in stock.
HIGH-VOLUME Describes a popular item, which is sold in large numbers.	STOCK ORDER A process by which the store orders more stock from its suppliers in order to maintain its inventory.
INDIVIDUALLY PRICED The condition of having each part of a display priced for customer convenience.	STOCK ROTATION Selling the older stock on hand before selling the newer stock.
INVENTORY The parts a store or shop has in its possession for resale.	SUPERSESSION BULLETIN A bulletin sent by the parts supplier that lists part numbers that now replace (supersede) previous part numbers.
INVENTORY CONTROL A method of determining amounts of merchandise to order based on supplies on hand and past sales of the item.	TURNOVER The number of times each year that a business buys, sells, and replaces a part.
INVOICE The record of a sale to a customer.	VENDOR The supplier.
JOBBER The owner or operator of an auto parts store usually wholesaling products to volume purchasers such as dealers, fleet owners, and businesses. They also may sell retail to do-it-yourselfers.	WARRANTY RETURN A defective part returned to the supplier due to failure during its warranty period.
LIST PRICE The suggested selling price for an item.	WAREHOUSE DISTRIBUTOR The jobber's supplier who is the link between the manufacturer and the jobber.
MARGIN Same as gross profit.	WHOLESALE The business's price to large-volume customers.
MARKUP The amount a business charges for a part above the actual cost of the part.	

Figure 1-17 Some of the common terms used by parts personnel.

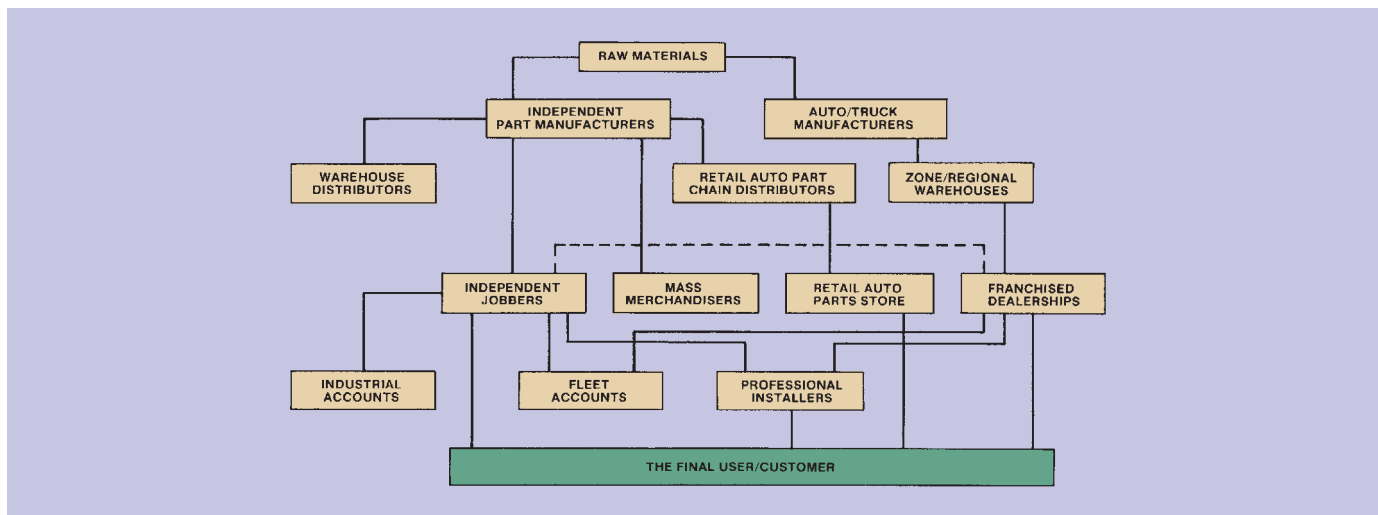

Figure 1-18 The auto parts supply network.

Figure 1-19 Many parts stores are part of a national corporation with stores located across the country.

Figure 1-20 A career possibility for an experienced technician is that of a trainer for the various manufacturers or instructors for an automotive program.

trainer; however, passing on knowledge can be very rewarding. Undoubtedly, there is no other career that can have as much impact on the automotive service industry as that of a trainer or instructor.

TRAINING FOR A CAREER IN AUTOMOTIVE SERVICE

Those interested in a career in auto service can receive training in formal school settings—secondary, postsecondary, and vocational schools; and technical or community colleges, both private and public.

Student Work Experience

There are many ways to gain work experience while you are a student. You may already be involved in one of the following; if not, consider becoming involved in one of these possibilities.

Job Shadowing Program In this program you follow an experienced technician or service writer. The pri-

mary program objective is to expose you to the “real world,” to see what it takes to be a successful technician or service writer. By job shadowing, you will also become familiar with the total operation of a service department.

Mentoring Program This program has the lowest participation rate of all these programs but can be one of the most valuable. In a mentoring program, you have someone who is successful to use as an expert. Your mentor has agreed to stay in contact with you, to answer questions, and to encourage you. When you have a good mentor, you have someone who may be able to explain things a little differently than the way things are explained in class. A mentor may also be able to give real life examples of why some of the things you need to learn are important.

Cooperative Education This type of program is typically 2 years in length. One year is spent in school and

the other in a dealership or service facility. This does not mean that 1 solid year is spent in school; rather you spend 8 to 12 weeks at school, and then work for 8 to 12 weeks. The switching back and forth continues for 2 years. Not only do you earn an hourly wage while you are working, you also earn credit toward your degree or diploma. While at work, you get a chance to practice and perfect what you learned in school. Your experiences at work are carefully coordinated with your experiences at school; therefore, it is called a cooperative program—industry cooperates with education. Examples of this type of program are the Chrysler CAPS, Ford ASSET, GM ASEP, and Toyota T-Ten (in Canada these are called T-TEP) programs.

Apprenticeship Program Similar to a cooperative education program, an apprenticeship program combines work experiences with education. The primary difference between the two programs is that in an apprenticeship program students attend classes in the evening after completing a day's work. During this rigorous training program, you receive a decent hourly wage and plenty of good experience. You start the program as a helper to an experienced technician and can begin to do more on your own as you progress through the program. Most apprenticeship programs take 2 years to complete. Automobile manufacturers and dealers often sponsor these programs.

Part-Time Employment The success of this experience depends on you and your drive to learn. Working part-time will bring you good experience, some income, and a good start in getting a great full-time position after you have completed school. The best way to approach this is to find a position and service facility that will allow you to grow. You need to start at a right level and be able to take on more difficult tasks when you are ready. The most difficult challenge when working part-time is to keep up with your education while you are working. Many times work may get in the way, but if you truly want to learn, you will find a way to fit your educational needs around your work schedule.

Postgraduate Education A few manufacturer programs are designed for graduates of postsecondary schools. These programs train individuals to work on particular vehicles. For example, BMW's Service Technician Education Program (STEP) is a scholarship program for the top graduates of automotive postsecondary schools. Students in the program apply what they learned in their 2-year program and learn to diagnose and service BMW products. BMW says this program is the most respected and intense

training program of its kind in the world. For more information go to <http://www.bmwstep.com>.

The Need for Continuous Learning

Training in automotive technology and service does not end with graduation. Nor does the *need to read* end. A professional technician constantly learns and keeps up to date. In order to maintain your image as a professional and to keep your knowledge and skills up to date, you need to do what you can to learn new things. You need to commit yourself to lifelong learning.

There are many ways in which you can keep up with the changing technology. Short courses on specific systems or changes are available from the manufacturers and a number of companies that offer formal training, such as Federal Mogul, NAPA, AC Delco, and local parts jobbers. There are also several on-line courses available. It is wise to attend update classes as soon as you can. If you wait too long, you may have a difficult time catching up with the ever-changing technologies.

In addition to taking classes, you can learn by reading automotive magazines or the newest editions of automotive textbooks. A good technician takes advantage of every opportunity to learn.

ASE CERTIFICATION

The National Institute for **Automotive Service Excellence (ASE)** has established a voluntary certification program for automotive, heavy-duty truck, auto body repair, and engine machine shop technicians. In addition to these programs, ASE also offers individual testing in the areas of automotive and heavy-duty truck parts, service consultant, alternate fuels, advanced engine performance, and a variety of other areas. This certification system combines voluntary testing with on-the-job experience to confirm that technicians have the skills needed to work on today's more complex vehicles. ASE recognizes two distinct levels of service capability—the automotive technician and the master automotive technician. The master automotive technician is certified by ASE in all major automotive systems. The automotive technician may have certification in only several areas.

To become ASE certified, a technician must pass one or more tests that stress system diagnosis and repair procedures. The eight basic certification areas in automotive repair follow:

1. Engine repair
2. Automatic transmission/transaxle
3. Manual transmissions and drive axles
4. Suspension and steering

Figure 1-21 ASE certification shoulder patches worn by (left) automotive technicians and (right) master automotive technicians.

5. Brakes
6. Electrical systems
7. Heating and air conditioning
8. Engine performance (driveability)

After passing at least one exam and providing proof of 2 years of hands-on work experience, the technician becomes ASE certified. Retesting is necessary every 5 years to remain certified. A technician who passes one examination receives an automotive technician shoulder patch. The master automotive technician patch is awarded to technicians who pass all eight of the basic automotive certification exams (Figure 1-21).

ASE also offers advanced-level certification in some areas. The most commonly sought advanced certification for automobile technicians is the L1 or Advanced Engine Performance. Individuals seeking this certification must be certified in Electricity and Engine Performance before taking this exam.

ASE also offers specialist certifications. For example, to become a certified Undercar Specialist, you must have certification in Suspension and Steering, Brake, and Exhaust Systems (a speciality test). Certification is also available for Parts Counterperson and Service Consultants.

As mentioned, ASE certification requires that you have 2 years of full-time, hands-on working experience as an automotive technician. You may receive credit toward this 2-year experience requirement by completing formal training in one or a combination of the following:

- High school training
- Post-high school training
- Short courses
- Apprenticeship programs

Each certification test consists of forty to eighty multiple-choice questions. The questions are written by a panel of technical service experts, including domestic and import vehicle manufacturers, repair and test equipment and parts manufacturers, working automotive technicians, and automotive instructors. All questions are pretested and quality checked on a national sample of technicians before they are included in the actual test. Many test questions force the student to choose between two distinct repair or diagnostic methods.

For further information on the ASE certification program, go to its Web site at <http://www.ase.com>.

SUMMARY

- The modern auto industry is a global industry involving vehicle and parts manufacturers from many countries.
- Electronic computer controls are found on many auto systems, such as engines, ignition systems, transmissions, steering systems, and suspensions. The use of electronics in automobiles is increasing rapidly.
- Preventive maintenance is extremely important in keeping today's vehicles in good working order.
- New car dealerships, independent service shops, specialty service shops, fleet operators, and many other businesses are in great need of qualified service technicians.
- A solid background in auto technology may be the basis for many other types of careers within the industry. Some examples are parts management, collision damage appraisal, sales, and marketing positions.
- Training in auto technology is available from many types of secondary, vocational, and technical

schools. Auto manufacturers also have cooperative programs with schools to ensure that graduates understand modern systems and the equipment to service them.

- The National Institute for Automotive Service Excellence (ASE) actively promotes professionalism within the industry. Its voluntary certification program for automotive technicians and master auto technicians helps guarantee a high level of quality service.
- The ASE certification process involves both written tests and credit for on-the-job experience. Testing is available in many areas of auto technology.

REVIEW QUESTIONS

1. Give a brief explanation of why electronics are so widely used on today's vehicles.
2. Explain the basic requirements for becoming a successful automotive technician.
3. List at least five different types of businesses that hire service technicians. Describe the types of work these businesses handle and the advantages and disadvantages of working for them.
4. Name four ways that you can gain work experience while you are a student.
5. *True or False?* In most cooperative education programs, students work at an automotive service facility during the day and attend classes in the evenings.
6. Individuals often begin a career as an automotive technician in a new car dealership by _____, which is a good way for a new technician to become familiar with the vehicles sold at the dealership.
 - a. working at the parts counter
 - b. performing new car prep
 - c. being a service advisor
 - d. serving as the lead tech
7. *True or False?* A hybrid vehicle uses two different power sources.
8. The government-mandated warranty that specifically covers the catalytic converter(s) and engine control module is the _____.
 - a. Federal Emissions Defect Warranty
 - b. Federal Powertrain Warranty
 - c. Federal Emissions Performance Warranty
 - d. Extended Federal Exhaust Warranty
9. Which of the following is typically included in a scheduled preventive maintenance program?
 - a. oil and filter changes
 - b. coolant and lubrication services
 - c. replacement of filters
 - d. all of the above
10. In a large new car dealership, the individual who oversees the operation of the service department, parts department, and body shop is the _____.
 - a. service manager
 - b. service director
 - c. shop foreman
 - d. parts manager
11. Repair work performed on vehicles still under the manufacturer's warranty is usually performed by _____.
 - a. independent service shops
 - b. dealerships
 - c. specialty shops
 - d. either a or b
12. Which of the following businesses perform work on only one or two automotive systems?
 - a. dealerships
 - b. independent service shops
 - c. specialty shops
 - d. fleet service departments
13. Normally, whose job is it to greet the customer and complete the repair or work order?
 - a. service manager
 - b. parts manager
 - c. automotive technician
 - d. service advisor
14. Technician A says that all an individual needs to do in order to become certified by ASE in a particular area is to pass the certification exam in that area. Technician B says that all of the questions on an ASE exam force the test taker to choose between two distinct repair methods. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
15. To be successful, today's automotive technician must have _____.
 - a. an understanding of electronics
 - b. the ability to repair and service mechanical systems

- c. the dedication to always be learning something new
 - d. all of the above
16. A technician must have a minimum of _____ year(s) of hands-on work experience to get ASE certification.
- a. 1
 - b. 2
 - c. 3
 - d. 4
17. A technician who passes all eight basic ASE automotive certification tests is certified as a(n) _____.
- a. automotive technician
 - b. master automotive technician
 - c. service manager
 - d. parts manager
18. Technician A says battery warranties are often prorated. Technician B says prorated warranties have a deductible. Who is correct?
- a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
19. Wholesale auto parts stores that sell aftermarket parts and supplies to service shops and the general public are called _____.
- a. warehouse distributors
 - b. mass merchandisers
 - c. jobbers
 - d. freelancers
20. Ongoing technical training and support is available from _____.
- a. aftermarket parts manufacturers
 - b. auto manufacturers
 - c. jobbers
 - d. all of the above

WORKPLACE SKILLS

OBJECTIVES

- Develop a personal employment plan.
- Seek and apply for employment.
- Prepare a resume and cover letter.
- Prepare for an employment interview.
- Accept employment.
- Understand how automotive technicians are compensated.
- Understand the proper relationship between an employer and an employee.
- Explain the key elements of on-the-job communications.
- Be able to use critical thinking and problem-solving skills.
- Explain how you should look and act to be regarded as a professional.
- Explain how fellow workers and customers should be treated.

This chapter gives an overview of what you should do to get a job and how to keep it. The basis for this discussion is respect—respect for yourself, your employer, fellow employees, your customers, and everyone else. Also included in this discussion are the key personal characteristics required of all seeking to be successful automotive technicians and employees.

SEEKING AND APPLYING FOR EMPLOYMENT

Becoming employed, especially in the field in which you want a career, involves many steps. As with many things in life, you must be adequately prepared before taking the next step toward employment. This discussion suggests ways you can prepare and what to expect while taking these steps.

Employment Plan

An **employment plan** is nothing more than an honest appraisal of yourself and your career hopes. The plan should include your employment goals, a timetable for reaching those goals, and a prioritized list of potential employers or types of employers. You may need to share your employment plan with someone while you are seeking employment, so make sure it is complete. Even if no one else will see it, you should be as thorough as possible because it will help keep you focused during your quest for employment.

Think about the type of job you want and do some research to find out what is required to get that job. Evaluate yourself against those requirements. If you do not meet the requirements, set up a plan for obtaining the needed skills. Also, consider the working conditions of that type of job. Are you willing and able to be a productive worker in those conditions? If not, find a job that is similar to your desires and pursue that career.

Self-Appraisal To begin the self-appraisal part of your employment plan, ask yourself:

- Why am I looking for a job?
- What specifically do I hope to gain by having a job?
- What do I like to do?
- What am I good at?
- Which of my skills would I like to use in my job?

By honestly answering these questions, you should be able to identify the jobs that will help you meet your goals. If you are just seeking a job to pay bills or buy a car and have no intention of turning this job into a career, be honest with yourself and your potential employer. If you are hoping to begin a successful career, realize you will probably start at the bottom of the ladder to success. You must also realize that how quickly you climb the ladder is your responsibility. An employer's responsibility is merely to give you a fair chance to climb it.

Identifying Your Skills Honestly evaluate yourself and your life to determine what skills you have. Even if you have never had a job, you still have skills and talents that can make you a desirable employee. Make a list of all of the things you have learned from your school, friends, and family and through television, volunteering, books, hobbies, and so on. You may be surprised by the number of skills you have. Identify these skills as being either technical or personal skills.

Technical skills include things you can do well and enjoy, such as:

- Using a computer
- Working with tools, machines, or equipment
- Playing video games
- Doing math problems
- Maintaining or fixing things
- Figuring out how things work
- Making things with your hands
- Working with ideas and information
- Solving puzzles or problems
- Studying or reading
- Doing experiments or researching a topic
- Expressing yourself through writing

Personal skills are also called **soft skills** and are things that are part of your personality. These are things you are good at or enjoy doing, such as:

- Working with people
- Caring for or helping people
- Working as a member of a team and independently
- Leading or supervising others
- Following orders or instructions
- Persuading people
- Negotiating with others

By identifying these skills you will have created your personal skills inventory. From the inventory you match your skills and personal characteristics to the needs and desires of potential employers. The inventory will also come in handy when marketing yourself for a job, such as when preparing your resume and cover letter and during an interview.

Identifying Job Possibilities

One of the things you identified in your employment plan was your preferred place to work. This may have been a specific business or a type of business, such as a new car dealership or independent shop. Now your task is to identify the companies that are looking for

Figure 2-1 Check the help-wanted ads in your local newspaper for businesses that are looking for technicians.

someone. To do this, look through the help-wanted section in the newspaper (**Figure 2-1**). You can also check your school's job posting board or ask people you know who already work in the business. If there is nothing available in the business you prefer, look for openings in the type of business that was second on your priority list.

Carefully look at the description of the job. Make sure you meet the qualifications for the job before you apply. For example, if you have a drug problem and the ad states that all applicants will be drug tested, you should not bother applying and should concentrate on breaking the habit. Even if the ad says nothing about testing for drug use, you should know that there is no place for drugs at work and continued drug use will only jeopardize your career.

Driving Record Your driving record is something you must also be aware of, and you probably are. If you have a poor record, you may not be considered for a job that requires operating a vehicle. In the same way that a driving record affects your personal car insurance, the employer's insurance costs can also increase because of your poor driving record. A bad driving record or the loss of a driver's license can jeopardize getting or keeping a job.

Preparing Your Resume

Your **resume** and cover letter are your own personal marketing tools and may be the first look at you an

employer has. Although not all employers require a resume, you should prepare one for those that do. Preparing a resume also forces you to look at your qualifications for a job. That alone justifies having a resume.

Keep in mind that although you may spend hours writing and refining your resume, an employer may only take a minute or two from his or her busy schedule to look it over. With this in mind, put together a resume that tells the employer who you are in such a way that he or she wants to interview you.

A resume normally includes your contact information, career objective, skills and/or accomplishments, work experience, education, and a statement about references. There are different formats you can follow when designing your resume. If you have limited work experience, make sure the resume emphasizes your skills and accomplishments rather than work history. Even if you have no work experience, you can sell yourself by highlighting some of the skills and attributes you identified in your employment plan.

When listing or mentioning your attributes and skills, express them in a way that shows how they relate to the job you are seeking. For instance, if you practice every day at your favorite sport so you can make the team, you may want to describe yourself as being persistent, determined, motivated, and goal-oriented. Another example is if you have ever pulled an all-nighter to get an assignment done on time, it can mean that you work well under pressure and always get the job done. Another example would be if you keep your promises and do what you said you would do, you may want to describe yourself as reliable, a person who takes commitment seriously.

Identifying your skills may be a difficult task, so have your family and/or friends help you. Keep in mind that you have qualities and skills that employers want. You need to recognize them, put them in a resume, and tell them to your potential employer. Do not put the responsibility of figuring out who you are on the employers—tell them.

Figure 2-2 is an example of a basic resume for an individual seeking an entry-level position as a technician.

Putting Together an Effective Resume Follow these guidelines while preparing and writing your resume:

- Your resume must be typewritten. If you do not have access to a computer or a typewriter, your local library probably has them available for public use.
- Make sure it is neat, uncluttered, and easy to read.
- Use quality white paper.
- Keep it short—a maximum of one or two pages.
- Use dynamic words to describe your skills and experience, such as accomplished, achieved, communicated, completed, created, delivered, designed, developed, directed, established, founded, instructed, managed, operated, organized, participated, prepared, produced, provided, repaired, and supervised.
- Choose your words carefully; remember that the resume is a look at you.
- Make sure all information is accurate.
- Make sure the information you think is the most important stands out and is positioned near the top of the page.
- Design your resume with a clean letter type (font) and wide margins (1½ inches on both sides is good) so that it is easy on the eyes.
- Only list the “odd” jobs you had if they are related to the job you are applying for.
- Do not repeat information.
- Proofread the entire resume to catch spelling and grammatical errors. If you find them, fix them and print a new, clean copy.
- Do not make handwritten corrections or use correction fluid to cover mistakes.
- Make sure your resume is not dirty and wrinkled when you deliver it.

References

A **reference** is someone who will be glad to tell a potential employer about you. A reference can be anyone who knows you, other than a family member or close friend. Employers contact references to verify or complete their picture of you. Make a list of three to five people you can use as references, including their contact information. If you do not supply references, the potential employer may assume that you cannot find anyone who has anything nice to say about you. You probably will not be considered for the job.

Choose your references wisely. Teachers (past and present), coaches, and school administrators are good examples of who you can ask to be a reference. People you have worked for or have helped are also good references. Try also to get someone whose opinion is respected, such as a priest, minister, or elder in your church or someone you know well who holds a high position.

Always talk to your references first, and get permission to give their names and telephone numbers to an employer. If they do not seem comfortable with

Somewhere, OZ 99902
123-456-7890

Performance-oriented student, with an excellent reputation as a responsible and hard-working achiever, seeking a position as an entry-level automotive technician in a new car dealership.

Skills and Attributes

- People oriented
- Motivated
- Committed
- Strong communication and teamwork skills
- Honest
- Reliable
- Organized
- Methodical
- Creative problem-solver
- Good hand skills

Work Experience

2006–2008 Somewhere Soccer Association (Assistant coach)

- Instructed and supervised junior team
- Performed administrative tasks as the Coach required

2004–2006 Carried out various odd jobs within the community

- Washing and waxing cars, picking up children from school, raking leaves, cutting grass

Education

Somewhere Senior High School, graduated in 2008
Somewhere Community College, currently enrolled in the Automotive Technology Program

Extracurricular Activities

1999–2008 Active member of the video game club
1999–2008 Member of the varsity soccer team

Hobbies and Activities

Reading auto-related magazines, going to races, doing puzzles, working on cars with family and friends.

References

Available upon request.

giving you a reference, take the hint and move on to someone else. If someone is willing to provide you with a written reference, make several copies of the letter so you can attach them to your resume and/or job application. Give copies of your resume to those on your reference list. Make sure to bring your reference list when applying for a job.

Preparing Your Cover Letter

A cover letter (**Figure 2-3**) should be sent with every resume you mail, e-mail, fax, or personally deliver. A cover letter gives you a chance to point out exactly why you are perfect for the job. You should not send out the same cover letter to all potential employers. Adjust the letter to match the company and position

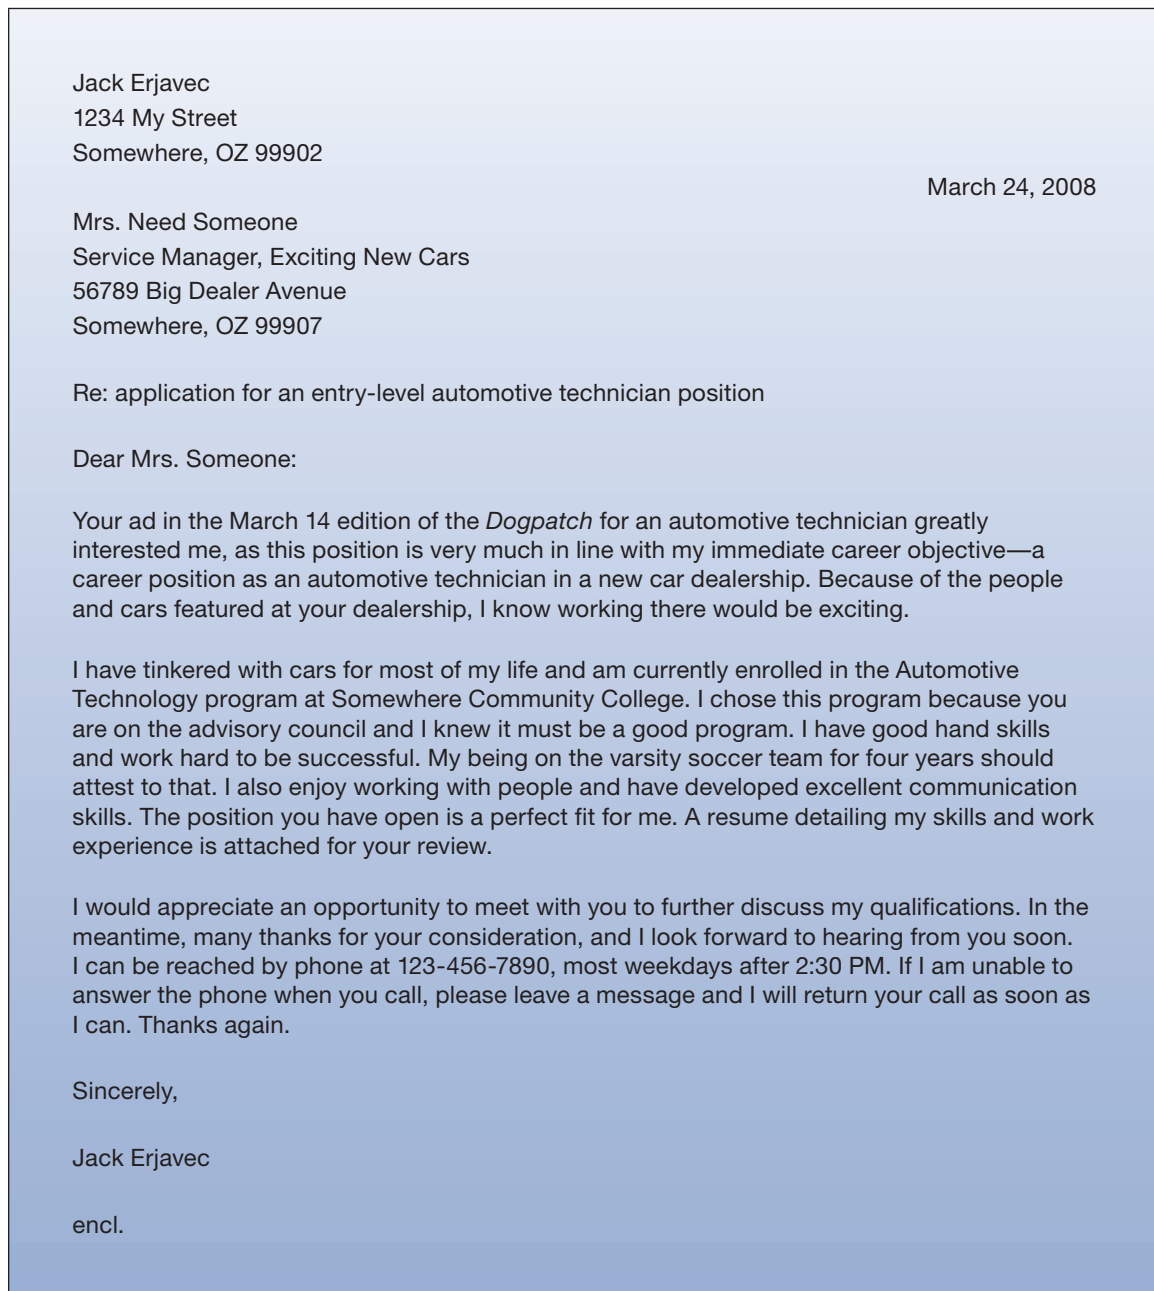

Figure 2-3 An example of a cover letter that can be sent with the resume in Figure 2-2.

you are applying for. Yes, this means a little more work, but it will be worth it. For example, if you state in one letter that you have always been a “Chevy nut” that may help at a Chevrolet dealership but will not at a Toyota or Ford dealership.

A good cover letter is normally made up of three paragraphs, each with its own purpose.

First Paragraph In the first paragraph, tell the employer that you are interested in working for the company, the position you are interested in, and why. Make sure you let the employer know that you know something about the company and what the job

involves. Also include a statement of how you found out about the open position, which could be a help-wanted ad, a job posting at school, and/or a referral by someone who works for the company.

Second Paragraph In this paragraph, sell yourself by mentioning one or two of your job qualifications and describe them in more detail than you did in your resume. Make sure you expand on the material in your resume rather than simply repeat it. Point out any special training or experience you have that directly relates to the job. When doing this, give a summary without listing the places and dates. This

information is listed in your resume so simply refer to the resume for details. This summary is another opportunity for you to let the employer know that you understand what they do, what the job involves, and how you can help them.

Third Paragraph Typically this paragraph is the end or closing of the letter. Make sure you thank the employer for taking the time to review your resume and ask him or her to contact you to make an appointment for an interview. Make sure you give a phone number where you can be reached. If you have particular times when it is best to contact you, put those times in this paragraph. Make sure you have a clear and understandable message on your telephone's answering machine, just in case you miss the employer's call. Also, have an organized work area around the phone so you can accurately schedule any interview appointments.

Guidelines for Writing an Effective Cover Letter Follow these guidelines while preparing and writing your cover letter:

- Address the letter to a person, not just a title. If you do not know the person's name, call the company and ask for the correct spelling of the person's name and his or her title.
- Make sure the words you use in the letter are upbeat.
- Use a natural writing style, keeping it professional but friendly.
- Try hard not to start every sentence with "I"; make some "you" statements.
- Check the letter for spelling and grammatical errors.
- Type the letter on quality paper and make sure it is neat and clean.
- Make sure you sign the letter before sending it.

Contacting Potential Employers

Unless the help-wanted ad or job posting tells you otherwise, it is best to drop your resume and cover letter off in person (preferably to the person who does the hiring). When you are doing this, make sure you tell the employer who you are and the job you want. Make sure you are prepared for what happens next. You may be given an interview right then. You may be asked to fill out an application. If so, fill it out.

Before you leave, thank the employer and ask if you can call back in a few days if you do not hear from him. If you do not hear back within a week, call to make sure the employer received your resume,

reminding him of who you are and what job you applied for. If he tells you that the job is filled or that no jobs are available, politely thank him for considering you and tell him you will stay in touch in case there is a future job opening.

Employment Application

An application for employment is a legal document that summarizes who you are. It is also another marketing tool for you. Filling out the application is the first task the employer has asked you to do, so do it thoroughly and carefully. Make sure you are prepared to fill out an application before you go. Take your own pen and a paperclip so that you can attach your resume to the application. Make sure you have your reference list. When filling out the application, neatly print your answers.

Read over the entire application before filling it out. Make sure you follow the directions carefully. Too often applicants try to rush through the application and make mistakes or provide the wrong information. Also by reading through the application before you fill in the blanks, you have a better chance of filling it out neatly. A messy application or one with crossed out or poorly erased information tells employers you may not care about the quality of your work.

By following the directions and providing the employer with the information asked for, you are demonstrating that you have the ability to read, understand, and follow written instructions, rules, and procedures. When answering the questions, be honest.

Make sure you completely fill out the application. Doing this shows the employer that you can complete a task. Answer every question. Write N/A (nonapplicable) if a question does not apply to you. If lines are left blank, the employer may think you do not pay attention to the details of a job or are a bit lazy. When you have completed the application, sign it and attach your cover letter and resume to it.

The Interview

Typically if employers are interested in you, you will be contacted to come in for an interview. This is a good sign. If they were not impressed with what they know of you so far, they will not ask for an interview. Knowing this should give you some confidence as you prepare for the interview.

Although an interview does not last very long, it is a time when you can either get the job or lose it.

Get ready for the interview by taking time to learn as much as you can about the company. Think of some of the reasons the company should hire you. When doing this, think of how both of you would

benefit. Think of questions you might ask the interviewer to show you are interested in the job and the business. Then make a list of questions that you think the employer might ask. Think about how you should answer each of them and practice the answers with your family and friends. Some of the more common interview questions include:

- What can you tell me about yourself?
- Why are you interested in this job?
- What are your strengths and weaknesses?
- If we employ you, what will you do for us?
- Do you have any questions about us or the job?

Tips for a Successful Interview

- Before the interview, think about what days and hours you can work and when you can start working.
- Make sure you take your social security card (or SIN card), extra copies of your resume, a list of your references and their contact information, as well as copies of any letters of recommendation you may have.
- Take paper and a pen to the interview so you can take notes. Often the interviewer will be doing the same.
- Try to relax right before the interview.
- Be on time (early is good) for the interview. If you are not exactly sure how to get to the business or what types of problems you may face getting there (such as traffic jams or construction), make a trip there 1 or 2 days before the interview. If you must be late, or if you cannot make it to the interview, call the employer as soon as possible and explain why. Ask if you can arrange for a new interview time.
- Show up looking neat and professional. Wear something more formal than what you would wear on the job.
- When you are greeted by the interviewer, introduce yourself and be ready to shake hands. Do it firmly!
- Listen closely to the interviewer and look at the interviewer while he or she talks.
- Answer all questions carefully and honestly. If you do not have an immediate answer, think about it before you open your mouth. If you do not understand the question, restate the question in the way you understand it. The interviewer will then know what question you are answering.
- Never answer questions with a simple “yes” or “no.” Answer all questions with examples or explanations that show your qualities or skills.

- Market yourself but do not lie about or exaggerate your abilities.
- Show your desire and enthusiasm for the job, but try to be yourself; that is, not too shy or too aggressive.
- Never say anything negative about other people or past employers.
- Do not be overly familiar with the interviewer and do not use slang during the interview, even if the interviewer does.
- Restate your interest in the job and summarize your good points at the end of the interview.
- Ask the interviewer if you can call back in a few days.

After the Interview

After the interview, go to a quiet place and reflect on what just took place. Think about what you did well and what you could have done better. Write these down so you can refer to them when you are preparing for your next interview.

Within 3 days after the interview, write a letter to the interviewer, thanking him or her for his or her time. Make sure you remind the interviewer of your interest and qualifications. Take advantage of this additional chance to market yourself but do not be overly aggressive when doing this.

Remember, finding a job takes time and seldom do you land a job on your first attempt. If you do not get a job offer as a result of a first interview, do not give up. Do your best not to feel depressed or dejected. Simply realize that, although you are qualified, someone with more experience was chosen. Send a thank-you letter anyway; this may prompt the interviewer to think of you the next time a similar job becomes available.

Review your cover letter, resume, and interview experience. Identify anything that can improve your marketing tools. Do not feel shy about asking the employer who did not hire you what you could have done better. Discuss your job hunt with your family and friends who will provide support and encouragement. Keep in touch with people you know who are working and who may have job leads. Explore other options. Do not rule out volunteering or job shadowing as a means of connecting with the workplace.

If you do get a job offer, do not be afraid to discuss the terms and conditions before accepting. Find out, or confirm, things such as what you will be doing, the hours you will be working, how you will be paid, and what to do when you report to work the first day. If you have any concerns, do not hesitate to share them with someone whose opinion you respect before

committing yourself to the job. Do not commit to the job and then change your mind a few days later. If you have any doubts about the job, think seriously about it before you accept or decline.

ACCEPTING EMPLOYMENT

When you accept the job, you are entering into an agreement with the employer. That agreement needs to be honored. Make sure you are ready to start working. You need to have transportation to and from work and the required tools and clothes for the job.

You will also need a social security (or, in Canada, a social insurance) number. If you do not already have one, you need one quickly. In the United States, you can apply for a social security number if you are a legal citizen or if you have a nonimmigrant visa status and have permission to work in the United States.

To apply for a social security number, you must appear in person at a Social Security office to complete the application form. You must take your birth certificate or valid passport with the necessary cards and authorizations to be employed. Once the forms are completed and submitted, it may take more than 2 weeks for you to receive a card with your number on it.

Typically before you begin to work, or at least before you get paid, you will fill out state and federal income tax forms. These forms give the company authorization to deduct income taxes from your wages. When you are an employee for a company, the

company must deduct those taxes. One form you will fill out is the employees withholding allowance certificate form, called the W-4. This form tells the employer how much, according to a scale, should be deducted from your pay for taxes. Basically the form asks how many exemptions you would like to claim. What you should claim depends on many things, and it is best that you seek advice from someone before you fill this in. In fact, do this well before you arrive to fill out the form.

Compensation

Automotive technicians (**Figure 2-4**) can be paid in a number of ways. When deciding on whether or not to accept a job, make sure you understand how you will be paid. Keep in mind that the employer agrees to pay you in exchange for your work, the quality of which is unknown before you start to work. When you accept employment, you accept the terms of compensation offered to you. Do not show up on the first day of work demanding more. After you have started working, progressed on the job, and made the company money, you can ask for more.

Hourly Wages Most often, new or apprentice technicians are paid a fixed wage for every hour they work. The amount of pay per hour depends on the business, your skill levels, and the work you will be doing. While collecting an hourly wage, you have a chance to learn the trade and the business. Time is usually spent working with a master technician or doing low-skilled

Figure 2-4 Automotive technicians can be paid in a number of ways.

jobs. As you learn more and become more productive, you can earn more. Many shops pay a good hourly rate to their productive technicians. Some have bonus plans that allow technicians to make more when they are highly productive. Nearly all service facilities for fleets pay their technicians an hourly wage.

Commission When technicians are paid on a **commission** basis, they receive a minimum hourly wage plus a percentage of what the shop receives from the customers for performing various services. This pay system can work well for technicians who are employed in a shop whose business fluctuates through the year. This system, along with the “flat-rate” system, is often referred to as incentive pay systems.

Flat Rate **Flat rate** is a pay system in which a technician is paid for the amount of work he or she does. The flat-rate system favors technicians who work in a shop that has a large volume of work. Although this pay plan offers excellent wages, it is not recommended for new and inexperienced technicians.

Every conceivable service to every different model of vehicle has a flat-rate time. These times are assigned by the automobile manufacturers. The times are based on the average time it takes a team of technicians to perform the service on new vehicle models. Flat-rate times (**Figure 2–5**) are listed in a **labor guide**, which can be a manual or be available on a computer. When you are paid on a flat-rate basis, your pay is based on that time, regardless of how long it took to complete the job. Flat-rate times are also used to determine the amount of money the dealership will receive from the manufacturer for making warranty repairs.

To explain how this system works, suppose a technician is paid \$15.00 per hour flat rate. If a job has a flat rate time of 3 hours, the technician will be paid \$45.00 for the job, regardless of how long it took to complete it. Experienced technicians beat the flat-rate time nearly all of the time. Their weekly pay is based on the time “turned in,” not on the time spent. If the technician turns in 60 hours of work in a 40-hour workweek, he or she actually earns \$22.50 each hour worked. However, if the technician turns in only 30 hours in the 40-hour week, the hourly pay is \$11.25.

The flat-rate times from the manufacturers are used primarily for warranty repairs. Once a vehicle gets a little older, it takes a little longer to service it. This is because dirt, rust, and other conditions make the services more difficult. Because of this, the flat-

rate times for older vehicles are longer. Because nondealership service facilities normally work on “out-of-warranty” vehicles, therefore older vehicles, the flat-rate times are about 20% higher than those used in a dealership. These flat-rate times are given in flat-rate manuals published by Chilton, Motor, and Mitchell.

At times, a flat-rate technician will be paid for the amount of time spent on the job. This is commonly referred to as “straight” or “clock” time. Straight time is paid when a service procedure is not listed in the flat-rate manual and when the customer’s concern requires more than normal diagnostic time.

Benefits Along with the pay, the employer may offer benefits, sometimes called “fringe benefits.” The cost of the benefits may be paid for by the business, or you may need to pay a share or all of the costs. There is no common benefit package for automotive technicians. Common benefits include:

- Health insurance
- Retirement plans
- Paid vacations
- Paid sick days
- Uniforms and uniform cleaning services
- Update training

When accepting employment, make sure you understand the benefits and seek help in choosing which you should participate in.

Total Earnings Depending on the business, you may be paid weekly or twice a month. The total amount of what you earn is called your **gross pay**. This is not your “take home” or **net pay**. Your net pay is the result of subtracting all taxes and benefit costs from your gross pay. These deductions may include:

- Federal income taxes
- State income taxes
- City income taxes
- Federal Insurance Contribution Act (FICA) taxes—this is commonly known as social security taxes
- Your contribution toward health insurance
- Uniform costs

WORKING AS A TECHNICIAN

Once you have the job, you need to keep it. Your performance during the first few weeks will determine how long you will stay employed and how soon you will get a raise or a promotion. Make sure you arrive to work on time. If you are going to be late or absent, call

HON-6

the employer as soon as you can. Once you are at work:

- Be cheerful and cooperative with those around you.
- Do not spend a lot of time talking when you should be working.
- Find out what is expected of you and do your best to meet those expectations.
- Make sure you ask about anything you are not sure of, but try to think things out for yourself whenever you can.
- Show that you are willing to learn and to help out in emergencies.

A successful automotive technician has a good understanding of how the various automotive systems work, has good hand skills, has a desire to succeed, and has a commitment to be a good employee. The required training is not just in the automotive field. Because good technicians spend a great deal of time working with service manuals, good reading skills are a must. Technicians must also be able to accurately describe what is wrong to customers and the service advisor. Often these descriptions are done in writing; therefore, a technician also needs to be able to write well.

Technicians also should have a basic knowledge of computers. Computers not only control the major systems of today's vehicles, they also are used for diagnostics, tracking customers, and record keeping and as sources for information. If you have little or no experience with computers, take a computer course and spend time using a computer. If you do not have access to one, go to your local library.

Employer-Employee Relationships

Being a good employee requires more than job skills. When you become an employee, you sell your time, skills, and efforts. In return, your employer has certain responsibilities:

- **Instruction and Supervision.** You should be told what is expected of you. Your work should be observed and you should be told if your work is satisfactory and offered ways to improve your performance.
- **Good Working Conditions.** An employer should provide a clean and safe work area as well as a place for personal cleanup.
- **Wages.** You should know how much you are to be paid and what your pay will be based on. Will you be paid by the hour, by the amount of work completed, or by a combination of these two?

Your employer should pay you on designated paydays.

- **Benefits.** When you were hired, you were told what fringe benefits you can expect. The employer should provide these when you are eligible to receive them.
- **Opportunity and Fair Treatment.** You should be given a chance to succeed and possibly advance within the company. You and all other employees should be treated equally, without prejudice or favoritism.

On the other side of this business relationship, you have responsibilities to the employer, including:

- **Regular Attendance.** A good employee is reliable. Businesses cannot operate successfully unless their workers are on the job. One of the first things a potential employer will ask an instructor is about the student's attendance.
- **Following Directions.** As an employee, you are part of a team. Doing things your way may not serve the best interests of the company.
- **Team Membership.** A good employee works well with others and strives to make the business successful.
- **Responsibility.** Be willing to answer for your behavior and work habits.
- **Productivity.** Remember that you are paid for your time as well as your skills and effort. You have a duty to be as effective as possible when you are at work.
- **Loyalty.** Loyalty is expected by any employer. This means you are expected to act in the best interests of your employer, both on and off the job.

COMMUNICATIONS

Employers value employees who can communicate. Effective communications include listening, reading, speaking, and writing. Communication is a two-way process. The basics of communication are simply sending a message and receiving a response.

To be successful, you should carefully follow all oral and written directions that pertain to your job. If you do not fully understand them, ask for clarification. You also need to be a good listener. Like other things in life, messages can appear to be good, bad, or have little worth to you. Regardless of how you rate the message, you should show respect to the person giving the message. Look at the person while he or she is speaking and listen to the message before you respond. In order to totally understand the message, you may need to ask questions and gather as many

Figure 2-6 Being able to read and understand the information and specifications given in service information is a must for automotive technicians. *Courtesy of Ford Motor Company*

details as possible. *Hint:* Try to put yourself in the other person's shoes and listen without bias.

Obviously, when you read something, you are receiving a message without the advantage of seeing the message sender. Therefore, you must take what you read at face value. This is important because being able to read and understand the information and specifications given in service information is necessary for automotive technicians (**Figure 2-6**).

Do your best to think through the words you use to convey a message to the customer or your supervisor. Pay attention to how they are listening and adjust your words and mannerisms accordingly. When writing a response, think about to whom the message is going and adjust your words to match their abilities and attitudes. Also, keep in mind that more than one person may read it, so think of others' needs as well.

Working in an automotive facility requires speaking to your supervisors, fellow employees, and

customers. Always keep in mind that communication is a two-way street; do not try to totally control the conversation, and give listeners a chance to speak.

Proper telephone etiquette is also important. Most businesses will tell you how to answer the phone, typically involving the name of the company followed by your name. Make sure you listen carefully to the person calling. When you are the one making the call, make sure you introduce yourself and state the overall purpose of the phone call. Again, the key to proper phone etiquette is respect.

You will also be required to write things, such as warranty reports and work orders. You may also need to speak with or write to customers, parts suppliers, and supervisors to clarify an issue. Take your time and write clear, concise, complete, and grammatically correct sentences and paragraphs. Doing this will not only help you to get your message across but will also make you a more prized employee.

Nonverbal Communication

In all communications, some of the true meaning is lost in the transmission of a message from a sender to a receiver. In many cases, the heard message is often far different from the one intended. Because the words spoken are not always understood or are interpreted wrongly because of personal feelings, you can alter the meaning of words significantly by changing the tone of your voice. Think of how many ways you can say "no"; you could express mild doubt, terror, amazement, anger, and other emotions.

It is important that you realize that a major part of communication is nonverbal. **Nonverbal communication** is the things you do while communicating. Pay attention to your nonverbal communication as well as to that of others.

Nonverbal communication includes such things as body language and tone. Body language includes facial expression, eye movement, posture, and gestures. All of us read people's faces; we interpret what they say or feel. We also look at posture to give us a glimpse of how the other person feels about the message. Posture can indicate self-confidence, aggressiveness, fear, guilt, or anxiety. Similarly, we look at how they place their hands or give a handshake.

Posture and other aspects of body language have been identified as important keys to communication. Many scholars have studied them and defined what they indicate. Some divide postures into two basic groups:

- **Open/closed** is the most obvious. People with their arms folded, legs crossed, and bodies turned away

are signaling that they are rejecting or are closed to messages, whereas people fully facing you with open hands and both feet planted on the ground are saying they are open to and accepting the message.

- *Forward/back* indicates whether people are actively or passively reacting to the message. When they are leaning forward and pointing toward you, they are actively accepting or rejecting the message. When they are leaning back, looking at the ceiling, doodling on a pad, or cleaning their glasses, they are either passively absorbing or ignoring the message.

SOLVING PROBLEMS AND CRITICAL THINKING

Anyone who can think critically and logically to evaluate situations is considered very desirable by the industry. **Critical thinking** is the art of being able to judge or evaluate something without bias or prejudice. When diagnosing an automotive problem, critical thinkers are able to locate the cause of the problem by responding to what is known, not what is supposed!

Good critical thinkers begin solving problems by carefully observing what is and what is not happening. Based on these observations, something is declared as a fact. For example, if the right headlamp of a vehicle does not light and the left headlamp does, a critical thinker will be quite sure that the source of the problem is related to the right headlamp and not the left one. Therefore, all testing will be centered on the right headlamp. The critical thinker then studies the circuit and determines the test points. Prior to conducting any test, the critical thinker knows what to test and what the possible test results would indicate.

Critical thinkers solve problems in an orderly way and do not depend on chance. They come to conclusions based on a sound reasoning. They also understand that if a specific problem exists only during certain conditions, there are a limited number of causes. They further understand the relationship between how often the problem occurs and the probability of accurately predicting the problem. Also, they understand that one problem may cause other problems and they know how to identify the connection between the problems.

Solving problems is something we do every day. Often the problems are trivial, such as deciding what to watch on television. Other times they are critical and demand much thought. At these times, thinking critically will really pay off. Although it is impossible

to guarantee that critical thinking will lead to the correct decision, it will lead to good decisions and solutions.

Diagnosis

The word **diagnosis** is used to define one of the major duties of a technician. Diagnosis is a way of looking at systems that are not functioning properly and finding out why. It is not guessing, and it is more than following a series of interrelated steps in order to find the solution to a specific problem. Solid diagnosis is based on an understanding of the purpose and operation of the system that is not working properly.

In service manuals there are diagnostic aids given for many different problems. These are either symptom based or flow charts. **Flow charts** or decision trees (**Figure 2-7**) guide you through a step-by-step process. As you answer the questions given at each step, you are told what your next step should be. Symptom-based diagnostic charts (**Figure 2-8**) focus on a definition of the problem and offer a list of possible causes of the problem. Sometimes the diagnostic aids are a combination of the two—a flow chart based on clearly defined symptoms.

When these diagnostic aids are not available or prove to be ineffective, most good technicians conduct a good visual inspection and then take a logical approach to finding the cause of the problem. This relies on critical thinking skills as well as system knowledge. Logical diagnosis follows these steps:

1. **Gather information about the problem.** Find out when and where the problem happens and what exactly happens.
2. **Verify that the problem exists.** Take the vehicle for a road test and try to duplicate the problem, if possible.
3. **Thoroughly define what the problem is and when it occurs.** Pay strict attention to the conditions present when the problem happens. Also pay attention to the entire vehicle; another problem may be evident to you that was not evident to the customer.
4. **Research all available information** to determine the possible causes of the problem. Try to match the exact problem with a symptoms chart or think about what is happening and match a system or some components to the problem.
5. **Isolate the problem** by testing. Narrow down the probable causes of the problem by checking the obvious or easy-to-check items.

DTC B3138 DOOR LOCK CIRCUIT (HIGH)

STEP	ACTION	YES	NO
1	Was a BCM diagnostic check performed?	Go to step 2	See BCM diagnostics
2	* Check for current DTCs with a scan tool. * Disconnect power to the LH door lock switch. * Does the scan tool display B3138 as a current code?	Go to step 3	Go to step 6
3	* Check for current DTCs with a scan tool. * Disconnect power to the RH door lock switch. * Does the scan tool display B3138 as a current code?	Go to step 4	Go to step 7
4	* Disconnect the brown BCM (C1) connector. * Backprobe connectors with a digital multimeter. * Measure voltage between A4 (LT BLU) and ground. * Does the multimeter show battery voltage?	Go to step 5	Go to step 8
5	Locate and repair the short to battery voltage in CKT 195 (LT BLU) between the BCM and the LOCK relay, or the left or right front door switches.	Go to step 9	—
6	Replace the LH power door lock switch. Is the repair complete?	Go to step 9	—
7	Replace the RH power door lock switch. Is the repair complete?	Go to step 9	—
8	* Replace the BCM. * Program the BCM with proper calibrations. * Perform the learn procedure. Is the repair complete?	Go to step 9	—
9	* Reconnect all disconnected components. * Clear the DTCs. Is the action complete?	System OK	—

Figure 2-7 A typical decision tree for diagnostics.

6. Continue testing to **pinpoint the cause of the problem**. Once you know where the problem should be, test until you find it!
7. **Locate and repair the problem, then verify the repair**. Never assume that your work solved the original problem. Make sure the problem is history before returning it to the customer.

PROFESSIONALISM

The key to effective communications is respect. Like communication, respect is a two-way process. You should respect others and others should respect you.

However, respect cannot be commanded; it must be earned. As a technician, you can earn respect in many ways. All of these result from the amount of professionalism you display. Professionalism is best shown by having a positive attitude, displaying good behavior, and accepting responsibility.

A good technician is a highly skilled and knowledgeable individual. A professional technician is a good technician who dresses and acts appropriately. A professional demonstrates the following:

- Self-esteem, pride, and confidence
- Honesty, integrity, and personal ethics

Symptom	Probable cause	Remedy
Engine will not start or hard to start	Vacuum hose disconnected or damaged	Repair or replace
	EGR valve is not closed	Repair or replace
	Malfunction of the EVAP Canister Purge	Repair or replace
	Solenoid Valve	Repair or replace
Rough idle or engine stalls	Vacuum hose disconnected or damaged	Repair or replace
	EGR valve is not closed	Repair or replace
	Malfunction of the PCV valve	Replace
	Malfunction of the EVAP Canister Purge System	Check the system; if there is a problem, check its component parts
Excessive oil consumption	Positive crankcase ventilation line clogged	Check positive crankcase ventilation system
Poor fuel mileage	Malfunction of the exhaust gas recirculation	Check the system; if there is a problem, check its component parts

Figure 2-8 A symptom-based diagnostic chart.

- A positive attitude toward learning, growth, and personal health
- Initiative, energy, and persistence to get the job done
- Respect for others
- A display of initiative and assertiveness
- The ability to set goals and priorities in work and personal life
- The ability to plan and manage time, money, and other resources to achieve goals
- The willingness to follow rules, regulations, and policies
- The willingness to fulfill the responsibilities of your job
- Assuming responsibility and accountability for your decisions and actions
- The ability to apply ethical reasoning

Coping with Change

Your professionalism is also evident by how you react to change. Unfortunately, work environments never stay the same. New rules and regulations, supervisors, fellow employees, business owners, and vehicle systems are all potential sources of stress. Rather than focusing on the negatives of these changes, you should identify the positives. This will help you minimize stress. If you feel stress, do what you can to relieve it. Activities such as walking, running, or playing sports help reduce stress. When you

are stressed, whether it is caused by something at work or in your personal life, it is difficult to be a productive worker. Therefore, do your best to put things in perspective and do some critical thinking to identify what you can do to change the situation that is causing the stress.

When the source of stress is related to your job, spend time to decide whether the stressful situation can be changed or not. If it cannot and you feel you can no longer cope with it, it may be wise to find employment elsewhere. This stress can be the result of change or can be caused by a realization that you do not like what you are doing or do not have the ability to do what is required of you.

If you decide that leaving your job is the best solution, do it professionally. Do not simply stop showing up for work or walk up to the employer and say “I quit!” The best way to quit a job is to write a letter of resignation and personally present it to the employer. The letter should state why you are leaving the company. Be careful not to attack the business, the employer, or fellow workers. You can simply say you are looking at other opportunities or have found another job. Bad-mouthing the business is a sure way of losing a good work reference—one that you may need for your next job. The letter should also include the last day you intend to work. Your last day should be approximately 2 weeks after you notify the employer. At the end of your letter of resignation, thank the employer for the opportunity to work for him or her and for the personal growth experiences they provided for you.

INTERPERSONAL RELATIONSHIPS

As an employee, you have responsibilities to your fellow workers. You are a member of a team. Teamwork means cooperating with and caring about other workers. All members of the team should understand and contribute to the goals of the business. Keep in mind that if the business does not make money, you may not have a job in the future. Your responsibility is more than simply doing your job. You should also:

- Suggest improvements that may make the business more successful.
- Display a positive attitude.
- Work with team members to achieve common goals.
- Respect the thoughts and opinions of your fellow workers and your employer.
- Exercise “give and take” for the benefit of the business.
- Value individual diversity.
- Respond to praise or criticism in a professional way.
- Provide constructive praise or criticism.
- Channel and control emotional reactions to situations.
- Resolve conflicts in a professional way.
- Identify and react to any intimidation or harassment.

Customer Relations

Good customer relations are important for all members of the team. You should make sure you listen and communicate clearly (**Figure 2-9**). Be polite and organized, particularly when dealing with customers

Figure 2-9 Good customer relations are important; make sure you always listen and communicate clearly.

on the telephone. Always be as honest as you possibly can.

Present yourself as a professional. Professionals are proud of what they do and they show it. Always dress and act appropriately and watch your language, even when you think no one is near.

Respect the vehicles you are working on. They are important to the lives of your customers. Always return the vehicles to their owners clean and in an undamaged condition. Remember, a vehicle is the second largest expense a customer has. Treat it that way. It does not matter if you like the vehicle. It belongs to the customer; treat it respectfully.

Explain the repair process to the customer in understandable terms. Whenever you are explaining something to a customer, make sure you do it in a simple way without making the customer feel stupid. Always show customers respect and be courteous to them. Not only is this the right thing to do but it also leads to loyal customers.

SUMMARY

- An employment plan is an honest appraisal of yourself and your career hopes.
- A reference is someone who will be glad to tell a potential employer about you and your work habits.
- A resume and cover letter are personal marketing tools and may be the first look at you an employer has.
- A resume normally includes your contact information, career objective, skills and/or accomplishments, work experience, education, and a statement about references.
- A cover letter gives you a chance to point out exactly why you are perfect for a particular job.
- An application form is a legal document that summarizes who you are.
- Good preparation for an employment interview will result in a good experience.

- Automotive technicians are typically paid an hourly wage or on the flat-rate system.
 - A successful automotive technician has good training, a desire to succeed, and a commitment to be a good technician and a good employee.
 - As part of an employment agreement your employer also has certain responsibilities to you, and you have responsibilities to the employer.
 - Effective communications include listening, reading, speaking, and writing.
 - Nonverbal communication is a key part of sending and receiving a message and includes such things as body language and tone.
 - Employers value someone who can think critically and act logically to evaluate situations and who has the ability to solve problems and make decisions.
 - Diagnosis means finding the cause or causes of a problem. It requires a thorough understanding of the purpose and operation of the various automotive systems.
 - Diagnostic charts found in service manuals can aid in diagnostics.
 - Professionalism is best displayed by having a positive attitude, displaying good behavior, and accepting responsibility.
 - New rules and regulations, supervisors, fellow employees, vehicle systems, and vehicles are all potential sources of stress, and your professionalism will be measured by how well you cope.
 - Teamwork means cooperating with and caring about other workers.
 - Good customer relations is a quality of good technicians and is based on respect.
2. What type of information should go into your employment plan?
 3. What does it mean to be paid based on flat rate?
 4. What should be included in the three main paragraphs of a cover letter?
 5. *True or False?* When you feel stress from your job and also feel that the situation will not change, you should seek employment elsewhere.
 6. Which of the following is *not* a desired characteristic of a good resume?
 - a. It is neat, uncluttered, and easy to read.
 - b. It has a list of all jobs you have done, whether for pay or just to help someone out.
 - c. It is only one or two pages long.
 - d. Important information appears near the top of the paper.
 7. Which of the following behaviors does *not* show that you are a responsible person?
 - a. having set goals and priorities in your work and personal life
 - b. showing a willingness to follow rules, regulations, and policies
 - c. showing a willingness to share the consequences of your mistakes with others
 - d. using ethical reasoning when making decisions
 8. *True or False?* If you decide that leaving your job is the best way to relieve stress at work, you should stop showing up for work and send your employer a letter stating why you left the company.
 9. *True or False?* When you are filling out an application, do not attempt to answer the questions that do not pertain to you and your situation.
 10. Which of the following is *not* the right thing to do when you are being interviewed for a job?
 - a. Show up looking neat and in the clothing you would wear on the job.
 - b. Never hesitate with an answer to a question, because hesitation may indicate you are a shy person.
 - c. To avoid saying too much or offending the interviewer, answer as many questions as you can with a simple yes or no.
 - d. Listen closely to the interviewer and look at the interviewer while he or she talks.
 11. Which of the following is *not* a characteristic of a good employee?

a. reliable	c. overly sociable
b. responsible	d. loyal

REVIEW QUESTIONS

1. Which of the following is *not* a recommended step for accurate diagnosis of a problem?
 - a. Gather as much information as you can about the problem.
 - b. Thoroughly define the problem.
 - c. Replace system components and identify the cause of a problem through the process of elimination.
 - d. Research all available information and knowledge to determine the possible causes of the problem.

12. Applicant A goes to a quiet place immediately after an interview and reflects on what just took place. Applicant B sends a letter of thanks to the interviewer if he has not heard back from the employer within 2 weeks. Who is doing the right thing?
 - a. A only
 - b. B only
 - c. Both A and B
 - d. Neither A nor B
13. Technician A always looks at people while they are speaking and listens to their message before responding. Technician B always looks at customers when they are speaking to show she is interested in what they are saying. Who is correct?
 - a. Technician A only
 - b. Technician B only
 - c. Both A and B
 - d. Neither A nor B
14. Technician A always speaks to customers with his arms folded across his chest because he does not know what else to do with them. Technician B always tries to fully comprehend the message by asking questions about it and gathering as many details as possible. Who is correct?
 - a. Technician A only
 - b. Technician B only
 - c. Both A and B
 - d. Neither A nor B
15. Which of the following would *not* be considered a soft skill?
 - a. enjoying solving puzzles or problems
 - b. caring for or helping people
 - c. the ability to work independently
 - d. taking care to follow orders or instructions
16. Describe the seven basic steps for logical diagnosis.
17. *True or False?* Critical thinking is the art of being able to judge or evaluate something with bias or prejudice.
18. *True or False?* The business you decide to work for will pay for all of the benefits you receive.
19. Define the term “diagnosis” as it applies to the duties of an automotive technician.
20. When identifying individuals to use as references while seeking employment, consider all of the following *except*:
 - a. someone who knows and whose opinion is respected, such as a priest, a minister, or an elder in your church
 - b. a family member or close friend
 - c. past and present teachers, coaches, and school administrators
 - d. people you have worked for or have helped

AUTOMOTIVE SYSTEMS

OBJECTIVES

- Explain the major events that have influenced the development of the automobile during the last 40 years.
- Explain the difference between unitized vehicles and body-over-frame vehicles.
- Describe the manufacturing process used in a modern automated automobile assembly plant.
- List the basic systems that make up an automobile and name their major components and functions.

HISTORICAL BACKGROUND

The automobile has changed quite a bit since the first horseless carriage went down an American street. In 1896, both Henry Ford and Ransom Eli Olds test drove their first gasoline-powered vehicles. Prior to this time, other individuals were making their own automobiles (**Figure 3-1**). Most were powered by electricity or steam. The year 1896 marks the beginning of the automotive industry, not because of what Ford or Olds did, but because of the Duryea Brothers, who, by 1896, had made thirteen cars in the first factory that made cars for customers.

In the beginning, the automobile looked like the horse-drawn carriage it was designed to replace. In

1919, 90% of the cars had carriagelike open bodies. These early cars had rear-mounted engines and very tall tires. They were designed to move people down dirt roads.

The automobile changed when the roads became paved, more people owned cars, manufacturers tried to sell more cars, concerns for safety and the environment grew, and new technology was developed. All of these changes resulted in automobiles that are more practical, more affordable, safer, more comfortable, more dependable, and faster. Although many improvements have been made to the original design, the basics of the automobile have changed very little:

- Nearly all of today's cars still use gasoline engines to drive two or more wheels.
- A steering system is used to control the direction of the car.
- A brake system is used to slow down and stop the car.
- A suspension system is used to absorb road shocks and help the driver maintain control on bumpy roads.
- These major systems are mounted on steel frames and the frame is covered with body panels.
- The body panels give the car its shape and protect those inside from the weather and dirt.
- The body panels also offer some protection for the passengers if the automobile is in an accident.

Although these basics have changed little in the past 100 years, the design of the systems has greatly

Figure 3-1 The 1886 Benz Patent Motor Wagen, one of the first automobiles made. © Courtesy of Daimler AG

changed. The entire automobile is technologically light-years ahead of Ford's and Olds's early models. New technologies have changed the slow, unreliable, user-hostile vehicles of the early 1900s into vehicles that can travel at very high speeds, operate trouble-free for thousands of miles, and provide comforts that even the very rich had not dreamed of in 1896.

Social and political pressures have had a great influence on automobile design for the past 40-plus years. In 1965, laws were passed that limited the amount of harmful gases emitted by an automobile. Although this had little immediate effect on the industry, the automobile manufacturers were forced to focus on the future. They needed to build cleaner-burning engines. In the following years, stricter emissions laws were passed and manufacturers were required to develop new emission control systems.

World events in the 1970s continued to shape the development of the automobile. An oil embargo by Arab nations in 1973 caused the price of gasoline to quickly increase to four times its normal price. This event caused most Americans to realize that the supply of gasoline and other nonrenewable resources was limited. Car buyers wanted cars that were not only kind to the environment but that also used less fuel.

The **Corporate Average Fuel Economy (CAFE)** standards were set in 1975. These required automakers to build more fuel-efficient vehicles. Under the CAFE standards, different models from each manufacturer are tested for the number of miles they can be driven on a gallon of gas. The fuel efficiencies of these vehicles are averaged together to arrive at a corporate average. The CAFE standards have increased many times since it was established. A manufacturer that does not meet CAFE standards for a given model year faces heavy fines.

While trying to produce more fuel-efficient vehicles, manufacturers replaced large eight-cylinder engines with four-cylinder and other small engines. Basic engine systems like carburetors and ignition breaker points were replaced by electronic fuel injection and electronic ignition systems.

By the mid-1980s, all automobiles were equipped with some type of electronic control system. These systems did, and still do, monitor the engine's operation and provide increased power outputs while minimizing fuel consumption and emissions. Electronic sensors are used to monitor the engine and many other systems. Computerized engine control systems control air and fuel delivery, ignition timing, emission systems operation, and a host of other related operations. The result is a clean-burning, fuel-efficient, and powerful engine (**Figure 3-2**).

Figure 3-2 A cutaway of a late-model V-10 gasoline engine.

DESIGN EVOLUTION

Not too long ago, nearly every car and truck was built with body-over-frame construction, rear-wheel drive, and symmetrical designs. Today, nearly all cars do not have a separate frame; instead, the frame and body are built as a single unit, called a unibody. Most pickup trucks and large SUVs still are built on a frame.

Another major influence to design was the switch from rear-wheel drive to front-wheel drive. Making this switch accomplished many things, the most notable being improved traction at the drive wheels, increased interior space, shorter hood lines, and a very compact driveline. Because of the weight and loads that pickup trucks are designed to move, most remain rear-wheel drive.

Perhaps the most obvious design change through the years has been body styles. Body styles have changed to respond to the other design considerations and to trends of the day. For example, in the '50s America had a strange preoccupation with the unknown, outer space, which led to cars that had rocketlike fins. Since then fins have disappeared and body styles have become more rounded to reduce air drag.

Body-Over-Frame Construction

In body-over-frame construction, the frame is the vehicle's foundation. The body and all major parts of the vehicle are attached to the frame. The frame must be strong enough to keep the rest of the vehicle in alignment should a collision occur.

The frame is an independent, separate component that is not rigidly attached to the vehicle's body. The body is generally bolted to the frame (**Figure 3-3**). Large, specially designed rubber mounts are placed between the frame and body to reduce noise and vibration from entering the passenger compartment. Quite often two layers of rubber are used in these pads

Figure 3-3 In body-over-frame construction, the frame is the vehicle's foundation. *Courtesy of Rob Lawrence and Toyota Motor Sales, U.S.A., Inc.*

to provide a smoother ride. The frame rails are made of stamped steel, which are welded together. Some frames are made by a **hydroforming** process, which uses high-pressure water, rather than heat, to shape the steel into the desired shape.

Unitized Construction

A **unibody** (Figure 3-4) is a stressed hull structure in which each of the body parts supplies structural support and strength to the entire vehicle. Unibody vehicles tend to be tightly constructed because the major parts are all welded together. This helps protect the occupants during a collision. However, it causes damage patterns that differ from those of body-over-frame vehicles. Rather than localized damage, the stiffer sections used in unibody design tend to transmit and distribute impact energy throughout more of the vehicle.

Figure 3-4 The structure of a unibody car. *Courtesy of BMW of North America, LLC*

Nearly all unibodies are constructed from steel. A few cars, such as the Audi A8, use aluminum instead. An aluminum car body and frame can weigh up to 40% less than an identical body made of steel. Most front-wheel-drive unibody vehicles have a **cradle** or partial frame that is used to support the powertrain and suspension for the front wheels.

BODY SHAPES

Various methods of classifying vehicles exist. Vehicles may be classified by engine type, body/frame construction, fuel consumption structure, type of drive, or the classifications most common to consumers, which are body shape, seat arrangement, and number of doors. Eight basic body shapes are used today:

- **Sedan.** A vehicle with front and back seats that accommodates four to six persons is classified as either a two- or four-door sedan (Figure 3-5). Often, a two-door sedan is called a coupe (Figure 3-6). If the vehicle's B pillars do not extend up through the side windows, the car is called a hardtop.

Figure 3-5 This Toyota Camry is an example of a typical late-model sedan. *Courtesy of Toyota Motor Sales, U.S.A., Inc.*

Figure 3-6 This Honda Civic SI is a coupe.

Figure 3-7 A BMW 3 series convertible. Courtesy of BMW of North America, LLC

- **Convertibles.** Convertibles have vinyl roofs that can be raised or lowered. A few late-model convertibles feature a folding metal roof that tucks away in the trunk when it is down (**Figure 3-7**). Some convertibles have both front and rear seats. Those without rear seats are commonly referred to as sports cars (**Figure 3-8**).
- **Liftback or hatchback.** The distinguishing feature of this vehicle is its rear luggage compartment, which is an extension of the passenger compartment. Access to the luggage compartment is gained through an upward opening hatch-type door (**Figure 3-9**). This design car can be a three- or a five-door model. The third or fifth door is the rear hatch.

Figure 3-8 This Aston Martin is an English sports car.

Figure 3-9 A Toyota Prius is an example of a hatchback. Its rear luggage compartment is an extension of the passenger compartment. Courtesy of Toyota Motor Sales, U.S.A., Inc.

- **Station wagon.** A station wagon is characterized by its roof, which extends straight back, allowing a spacious interior luggage compartment in the rear. The rear door, which can be opened in various ways depending on the model, provides access to the luggage compartment. Station wagons typically have four doors and can have space for up to nine passengers.
- **Pickups.** Pickup truck body designs have an open cargo area behind the driver's compartment. There are many varieties available today: there are compact, medium-sized, full-sized, and heavy-duty pickups. They also can be had in two-, three-, or four-door models. Some have extended cab areas with seats in back of the front seat. They are available in two-wheel drive, four-wheel drive (4X4), or all-wheel drive.
- **Vans.** The van body design has a tall roof and a totally enclosed large cargo or passenger area. Vans can seat from two to twelve passengers, depending on size and design. Basically, there are

Figure 3-10 This Dodge Caravan is an example of a late-model mini-van. Full-size vans are also available. Courtesy of Chrysler LLC

two sizes of vans: mini- and full-size. The most common are mini-vans (**Figure 3-10**).

■ **Sport utility vehicles (SUVs).** SUVs are best described as multipurpose vehicles that can carry a wide range of passengers, depending on their size and design. A good majority of SUVs have four-wheel drive, although some do not. Most small SUVs are based on automobile platform and take on many different looks and features (**Figure 3-11**). Mid-size SUVs are larger and typically offer more features and comfort. There are many large SUVs available (**Figure 3-12**). These vehicles can seat up to nine adults and tow up to 6 tons.

■ **Crossover vehicles.** These automobiles look like an SUV but are built lighter and offer fuel efficiency. They are actually a combination of a station wagon and an SUV. They have SUV features but are not quite the same size. The basic construction of a crossover vehicle leads to a less trucklike ride than a normal SUV (**Figure 3-13**). They also are not designed to tow heavy loads or for off-the-road use.

Figure 3-11 This Honda Element is considered a small SUV and has many unique features including anytime four-wheel drive.

Figure 3-12 This Lincoln Navigator is an excellent example of a large SUV, and it is based on a truck chassis.

Figure 3-13 This is an Audi crossover vehicle.

THE BASIC ENGINE

The engine provides the power to drive the wheels of the vehicle. All automobile engines, both gasoline and diesel, are classified as internal combustion engines because the combustion or burning that creates energy takes place inside the engine. **Combustion** is the burning of an air and fuel mixture. As a result of combustion, large amounts of pressure are generated in the engine. This pressure or energy is used to power the car. The engine must be built strong enough to hold the pressure and temperatures formed by combustion.

Diesel engines have been around a long time and are mostly found in big heavy-duty trucks. However, they are also used in some pickup trucks and will become more common in automobiles in the future (**Figure 3-14**). Although the construction of gasoline and diesel engines is similar, their operation is quite different.

A gasoline engine relies on a mixture of fuel and air that is ignited by a spark to produce power. A diesel engine also uses fuel and air, but it does not need a spark to cause ignition. A diesel engine is often called a compression ignition engine. This is because its incoming air is tightly compressed, which greatly raises its temperature. The fuel is then injected into

Figure 3-14 A four-cylinder automotive diesel engine.

the compressed air. The heat of the compressed air ignites the fuel and combustion takes place. The following sections cover the basic parts and the major systems of a gasoline engine.

Cylinder Block

The biggest part of the engine is the **cylinder block**, which is also called an **engine block** (Figure 3-15). The cylinder block is a large casting of metal (cast iron or aluminum) that is drilled with holes to allow for the passage of lubricants and coolant through the block and provide spaces for movement of mechanical parts. The block contains the cylinders, which are round passageways fitted with pistons. The block houses or holds the major mechanical parts of the engine.

Cylinder Head

The **cylinder head** fits on top of the cylinder block to close off and seal the top of the cylinders (Figure 3-16). The **combustion chamber** is an area into which the

Figure 3-15 An engine block for a V8 engine.

Figure 3-16 The two major units of an engine, the cylinder block and the cylinder head, are sealed together with a gasket and are bolted together. *Courtesy of Federal-Mogul Corporation*

air-fuel mixture is compressed and burned. The cylinder head contains all or most of the combustion chamber. The cylinder head also contains **ports**, which are passageways through which the air-fuel mixture enters and burned gases exit the cylinder. A cylinder head can be made of cast iron or aluminum.

Piston

The burning of air and fuel takes place between the cylinder head and the top of the piston. The **piston** is a can-shaped part closely fitted inside the cylinder (Figure 3-17). In a four-stroke cycle engine, the piston moves through four different movements or strokes to complete one cycle. These four are the intake, compression, power, and exhaust strokes. On the intake stroke, the piston moves downward, and a charge of air-fuel mixture is introduced into the cylinder. As the piston travels upward, the air-fuel mixture is compressed in preparation for burning. Just before the piston reaches the top of the cylinder, ignition occurs and combustion starts. The pressure of expanding gases forces the piston downward on its power stroke. When it reciprocates, or moves upward again, the piston is on the exhaust stroke. During the exhaust stroke, the piston pushes the burned gases out of the cylinder.

Connecting Rods and Crankshaft

The reciprocating motion of the pistons must be converted to rotary motion before it can drive the wheels

Figure 3-17 The engine's pistons fit tightly in the cylinders and are connected to the engine's crankshaft with connecting rods.

of a vehicle. This conversion is achieved by linking the piston to a **crankshaft** with a **connecting rod**. As the piston is pushed down on the power stroke, the connecting rod pushes on the crankshaft, causing it to rotate. The end of the crankshaft is connected to the transmission to continue the power flow through the drivetrain and to the wheels.

Valve Train

A **valve train** is a series of parts used to open and close the intake and exhaust ports. A valve is a movable part that opens and closes a passageway. A camshaft controls the movement of the valves (**Figure 3-18**), causing them to open and close at the proper time. Springs are used to help close the valves.

Figure 3-18 The valve train for one cylinder of an overhead valve engine.

Figure 3-19 The blue manifold is the intake manifold and the red manifold is for the exhaust.

Manifolds

A **manifold** is metal ductwork assembly used to direct the flow of gases to or from the combustion chambers. Two separate manifolds are attached to the cylinder head (**Figure 3-19**). The **intake manifold** delivers a mixture of air and fuel to the intake ports. The **exhaust manifold** mounts over the exhaust ports and carries exhaust gases away from the cylinders.

ENGINE SYSTEMS

The following sections present a brief explanation of the systems that help an engine run and keep running.

Lubrication System

The moving parts of an engine need constant lubrication. Lubrication limits the amount of wear and reduces the amount of friction in the engine. **Friction** is heat generated when two objects rub against each other.

Motor or engine oil is the fluid used to lubricate the engine. Several quarts of oil are stored in an **oil pan** bolted to the bottom of the engine block. The oil pan is also called the crankcase or **oil sump**. When the engine is running, an oil pump draws oil from the pan and forces it through oil galleries. These galleries are small passageways that direct the oil to the moving parts of the engine.

Oil from the pan passes through an oil filter before moving through the engine (**Figure 3-20**). The filter removes dirt and metal particles from the oil. Premature wear and damage to parts can result from dirt in the oil. Regular replacement of the oil filter and oil is an important step in a preventive maintenance program.

Figure 3-20 Oil flow in a typical engine's lubrication system.

Cooling System

The burning of the air-fuel mixture in the combustion chambers of the engine produces large amounts of heat. This heat must not be allowed to build up and must be reduced. This heat can easily damage and warp the metal parts of an engine. To prevent this, engines have a cooling system (**Figure 3-21**).

The most common way to cool an engine is to circulate a liquid coolant through passages in the engine block and cylinder head. An engine can also be cooled by passing air over and around the engine. Few air-cooled engines are used in automobiles today because it is very difficult to maintain a constant temperature at the cylinders. If the engine is kept at a constant temperature, it will run more efficiently.

A typical cooling system relies on a **water pump**, which circulates the coolant through the system. The pump is typically driven by the engine. The coolant is a mixture of water and antifreeze. The coolant is pushed through passages, called **water jackets**, in the cylinder block and head to remove heat from the area around the cylinders' combustion chambers. The heat picked up by the coolant is sent to the **radiator**. The radiator transfers the coolant's heat to the outside air as the coolant flows through its tubes. To help remove the heat from the coolant, a cooling fan is used to pull cool outside air through the fins of the radiator.

To raise the boiling point of the coolant, the cooling system is pressurized. To maintain this pressure, a radiator or **pressure cap** is fitted to the radiator. A **thermostat** is used to block off circulation in the system until a preset temperature is reached. This allows the engine to warm up faster. The thermostat also

Figure 3-21 A typical engine cooling system.

keeps the engine temperature at a predetermined level. Because parts of the cooling system are located in various spots under the vehicle's hood, hoses are used to connect these parts and keep the system sealed.

Fuel and Air System

The fuel and air system is designed to supply the correct amount of fuel mixed with the correct amount of air to the cylinders of the engine. This system also:

- Stores the fuel for later use
- Delivers fuel to a device that will control the amount of fuel going to the engine
- Collects and cleans the outside air
- Delivers outside air to the individual cylinders
- Changes the fuel and air ratios to meet the needs of the engine during different operating conditions

The fuel system is made up of different parts. A fuel tank stores the liquid gasoline. Fuel lines carry the liquid from the tank to the other parts of the system. A pump moves the gasoline from the tank through the lines. A filter removes dirt or other particles from the fuel. A fuel pressure regulator keeps the pressure below a specified level. An air filter cleans the outside air before it is delivered to the cylinders. Fuel injectors mix fuel with the air for delivery to the cylinders or directly to the cylinders. An intake manifold directs the air to each of the cylinders (Figure 3-22).

Emission Control System

In the past one of the chief contributors to air pollution was the automobile. For some time now, engines have been engineered to emit very low amounts of certain pollutants. The pollutants that have been drastically reduced are **hydrocarbons (HC)**, **carbon monoxide (CO)**, and **oxides of nitrogen (NO_x)**. The Environmental Protection Agency establishes emissions standards that limit the amount of these pollutants a vehicle can emit.

To meet these standards, many changes have been made to the engine itself. There also have been systems developed and added to the engines to reduce the pollutants they emit. A list of the most common pollution control devices follows:

- **Positive crankcase ventilation (PCV) system.** This system reduces HC emissions by drawing fuel and oil vapors from the crankcase and sends them into the intake manifold where they are delivered to and burned in the cylinders. This system prevents the pressurized vapors from escaping the engine and entering into the atmosphere.

Figure 3-22 The intake system for a V-10 in a Dodge Viper. Courtesy of Chrysler LLC

- **Evaporative emission control system.** This system reduces HC emissions by drawing fuel vapors from the fuel system and releases them into the intake air to be burned. This system stops these vapors from leaking into the atmosphere.
- **Exhaust gas recirculation (EGR) system.** This system introduces exhaust gases into the intake air to reduce the temperatures reached during combustion. This reduces the chances of forming NO_x during combustion.
- **Catalytic converter.** Located in the exhaust system, it allows for the burning or converting of HC, CO, and NO_x into harmless substances, such as water.
- **Air injection system.** This system reduces HC emissions by introducing fresh air into the exhaust stream to cause minor combustion of the HC in the engine's exhaust.

Exhaust System

During the exhaust stroke, the engine's pistons move up and push the burned air-fuel mixture, or exhaust, out of the combustion chamber and into the exhaust manifold. From the manifold, the gases travel through the other parts of the exhaust system until they are expelled into the atmosphere (Figure 3-23). The exhaust system is designed to direct toxic exhaust fumes away from the passenger compartment, to quiet the sound of the exhaust pulses, and to burn or

Figure 3-23 A typical exhaust system on a late-model car.

catalyze pollutants in the exhaust. A typical exhaust system contains the following components:

- Exhaust manifold and gasket
- Exhaust pipe, seal, and connector pipe
- Intermediate pipes
- Catalytic converter(s)
- Muffler and resonator
- Tailpipe
- Heat shields
- Clamps, gaskets, and hangers

ELECTRICAL AND ELECTRONIC SYSTEMS

Automobiles have many circuits that carry electrical current from the battery to individual components. The total electrical system includes such major sub-systems as the ignition system, starting system, charg-

ing system, and the lighting and other electrical systems.

Ignition System

After the air-fuel mixture has been delivered to the cylinder and compressed by the piston, it must be ignited. A gasoline engine uses an electrical spark to ignite the mixture. Generating this spark is the role of the ignition system.

The **ignition coil** generates the electricity that creates this spark (**Figure 3-24**). The coil transforms the low voltage of the battery into a burst of 30,000 to 100,000 volts. This burst is what ignites the mixture. The mixture must be ignited at the proper time in order for complete combustion to occur. Although the exact proper time varies with engine design, ignition must occur at a point before the piston has completed its compression stroke.

On most engines, the motion of the piston and the rotation of the crankshaft are monitored by a

Figure 3-24 An ignition module and coil assembly for four cylinders.

crankshaft position sensor. The sensor electronically tracks the position of the crankshaft and relays that information to an ignition control module. Based on input from the crankshaft position sensor, and, in some systems, the electronic engine control computer, the ignition control module then turns the battery current to the coil on and off at just the precise time so that the voltage surge arrives at the cylinder at the right time.

The voltage surge from the coil must be distributed to the correct cylinder because only one cylinder is fired at a time. In earlier systems, this was the job of the **distributor**. A distributor is driven by a gear on the camshaft at one-half the crankshaft speed. It transfers the high-voltage surges from the coil to spark plug wires in the correct firing order. The spark plug wires then deliver the high voltage to the spark plugs, which are screwed into the cylinder head. The voltage jumps across a space between two electrodes on the end of each **spark plug** and causes a spark. This spark ignites the air-fuel mixture.

Today's ignition systems do not use a distributor. Instead, these systems have several ignition coils—one for each spark plug or pair of spark plugs. When a coil is activated by the electronic control module, high voltage is sent through a spark plug circuit. The electronic control module has total control of the timing and distribution of the spark-producing voltage to the various cylinders.

Starting and Charging Systems

The starting system is responsible for getting the engine started (**Figure 3-25**). When the ignition key is turned to the start position, a small amount of current flows from the battery to a **solenoid** or relay. This activates the solenoid or relay and closes another electrical circuit that allows full battery voltage to reach the starter motor. The starter motor then rotates the flywheel mounted on the rear of the crankshaft. As the crankshaft turns, the pistons move through their strokes. At the correct time for each cylinder, the igni-

Figure 3-25 A typical starting system.

tion system provides the spark to ignite the air-fuel mixture. If good combustion takes place, the engine will now rotate on its own without the need of the starter motor. The ignition key is now allowed to return to the “on” position. From this point on, the engine will continue to run until the ignition key is turned off.

The electrical power for the engine and the rest of the car comes from the car's battery. The battery is especially important for the operation of the starting system. While the starter is rotating the crankshaft, it uses a lot of electricity. This tends to lower the amount of power in the battery. Therefore, a system is needed to recharge the battery so that engine starts can be made in the future.

The charging system is designed to recharge and maintain the battery's state of charge. It also provides electrical power for the ignition system, air conditioner, heater, lights, radio, and all electrical accessories when the engine is running.

The charging system includes an AC generator (alternator), voltage regulator, indicator light, and the necessary wiring. Rotated by the engine's crankshaft through a drive belt, the **AC generator** (**Figure 3-26**) converts mechanical energy into electrical energy. The AC is converted into direct current (DC) within the alternator. When the output or electrical current from the charging system flows back to the battery, the battery is being charged. When the current flows out of the battery, the battery is said to be discharging.

Electronic Engine Controls

Nearly all vehicles on the road have an electronic engine control system. This is a system comprised of many electronic and electromechanical parts. The system is designed to continuously monitor the operation of the engine and to make adjustments that will cause the engine to run more efficiently. Electronic

Figure 3-26 The major components of a late-model AC generator. Courtesy of Robert Bosch GmbH, www.bosch-presse.de

engine control systems have dramatically improved fuel mileage, engine performance, and driveability and have greatly reduced exhaust emissions.

Electronic control systems have three main types of components: input sensors, a computer, and output devices (**Figure 3-27**). The computer analyzes data from the input sensors. Then, based on the inputs and the instructions held in its memory, the computer directs the output devices to make the necessary changes in the operation of some engine

*1 : Except California Specification vehicles
*2 : Only for California Specification vehicles

Figure 3-27 Late-model electronic engine control systems are made up of many different sensors and actuators and a central computer or control module.

systems. Electronic control systems have fewer moving parts than old-style mechanical and vacuum controls. Therefore, the engine and other support systems can maintain their calibration almost indefinitely.

As an added advantage, an electronic control system is very flexible. Because it uses computers, it can be programmed to meet a variety of vehicle engine combinations or calibrations. Critical quantities that determine an engine's performance can be changed easily by changing data that is stored in the computer's memory.

On-Board Diagnostics

Today's engine control systems are **on-board diagnostic (OBD II)** second-generation systems. These systems were developed to ensure proper emission control system operation for the vehicle's lifetime by monitoring emission-related components and systems for deterioration and malfunction. This monitoring includes also a check of the tank ventilation system for vapor leaks. The OBD system consists of the engine and transmission control modules and their sensors and actuators along with the diagnostic software.

The computer (**Figure 3-28**) can detect system problems even before the driver notices a driveability problem because many problems that affect emissions can be electrical or even chemical in nature.

When the OBD system determines that a problem exists, a corresponding "diagnostic trouble code" is stored in the computer's memory. The computer also illuminates a yellow dashboard light indicating "check engine" or "service engine soon" or displays an engine symbol. This light informs the driver of the need for service, not of the need to stop the vehicle.

A blinking or flashing dashboard lamp indicates a rather severe level of engine misfire. When this occurs, the driver should reduce engine speed and load and

Figure 3-28 A typical automotive computer.

have the vehicle serviced as soon as possible. After the problem has been fixed, the dashboard lamp will be turned off.

HEATING AND AIR-CONDITIONING SYSTEMS

Heating and air-conditioning systems do little for the operation of a vehicle; they merely provide comfort for the passengers of the vehicle. Both systems are dependent on the proper operation of the engine. The heating system basically adds heat to the vehicle's interior, whereas air conditioning removes heat. To do this, the systems rely on many parts to put basic theories to work.

Heating Systems

To meet federal safety standards, all vehicles must be equipped with passenger compartment heating and windshield defrosting systems. The main components of an automotive heating system are the heater core, the heater control valve, the blower motor and the fan, and the heater and defroster ducts. The heating system works with the engine's cooling system and converts the heat from the coolant circulating inside the engine to hot air, which is blown into the passenger compartment. A heater hose transfers hot coolant from the engine to the heater control valve and then to the heater core inlet. As the coolant circulates through the core, heat is transferred from the coolant to the tubes and fins of the core. Air blown through the core by the blower motor and fan then picks up the heat from the surfaces of the core and transfers it into the passenger compartment. After giving up its heat, the coolant is then pumped out through the heater core outlet, where it is returned to the engine's cooling system to be heated again.

Transferring heated air from the heater core to the passenger compartment is the job of the heater and defroster ducts. The ducts are typically part of a large plastic shell that connects to the necessary inside and outside vents. Contained inside the duct are also the doors required to direct air to the floor, dash, and/or windshield.

Air-Conditioning Systems

An air-conditioning (A/C) system is designed to pump heat from one point to another. In an automotive A/C system, heat is removed from the passenger compartment and moved to the outside of the vehicle.

The substance used to remove heat from the inside of a vehicle is called the **refrigerant**. To understand how a refrigerant is used to cool the interior of a vehicle, the effects of pressure and temperature on it must be first understood. If the pressure of the refrigerant is

high, so is its temperature. Likewise if the pressure is low, so is its temperature. Therefore, changing its pressure can change the refrigerant's temperature.

To absorb heat, the temperature and pressure of the refrigerant are kept low. To get rid of the heat, the temperature and pressure are high. As the refrigerant absorbs heat, it evaporates or changes from a liquid to a vapor. As it dissipates heat, it condenses and changes from a vapor to a liquid. These two changes of state occur continuously as the refrigerant circulates through the system.

An A/C system is a closed, pressurized system. It consists of a compressor, condenser, receiver/dryer or accumulator, expansion valve or orifice tube, and an evaporator. The best way to understand the purpose of the components is to divide the system into two sides: the high side and the low side. High side refers to the side of the system that is under high pressure and high temperature. Low side refers to the low-pressure, low-temperature side (**Figure 3-29**).

Compressor The **compressor** separates the high and low sides of the system. Its primary purpose is to draw the low-pressure and low-temperature vapor from the evaporator and compress this vapor into high-temperature, high-pressure vapor. The secondary purpose of the compressor is to circulate or pump the refrigerant through the system. The compressor is located on the engine and is driven by the engine's crankshaft via a drive belt.

Compressors are equipped with an electromagnetic clutch as part of the compressor pulley

Figure 3-29 A simple look at an air conditioning system. The blue signifies low pressure and the red is high pressure.

assembly. The clutch is designed to engage the pulley to the compressor shaft when the clutch coil is energized. When the clutch is not engaged, the compressor shaft does not rotate, and the pulley freewheels. The clutch provides a way for turning the compressor on or off.

Condenser The **condenser** consists of coiled tubing mounted in a series of thin cooling fins to provide maximum heat transfer in a minimum amount of space. The condenser is normally mounted just in front of the vehicle's radiator. It receives the full flow of ram air from the movement of the vehicle or airflow from the radiator fan when the vehicle is standing still.

The condenser condenses or liquefies the high-pressure, high-temperature vapor coming from the compressor. To do so, it must give up its heat. Very hot, high-pressure refrigerant vapor enters the inlet at the top of the condenser, and as the hot vapor passes down through the condenser coils, heat moves from the refrigerant into the cooler air that flows across the coils and fins. This loss of heat causes the refrigerant to change from a high-pressure hot vapor to a high-pressure warm liquid. The high-pressure warm liquid flows from the bottom of the condenser to the receiver/dryer or to the refrigerant metering device if an accumulator is used.

Receiver/Dryer The **receiver/dryer** is a storage tank for the liquid refrigerant from the condenser. The refrigerant flows into the receiver tank, which contains a bag of desiccant (moisture-absorbing material). The desiccant absorbs unwanted water and moisture in the refrigerant.

Accumulator Most late-model systems have an accumulator rather than a receiver/dryer. The accumulator is connected into the low side at the outlet of the evaporator. The accumulator contains a desiccant and is designed to store excess refrigerant. If liquid refrigerant flows out of the evaporator, it will be collected by and stored in the accumulator. The main purpose of an accumulator is to prevent liquid from entering the compressor.

Thermostatic Expansion Valve/Orifice Tube The refrigerant flow to the evaporator must be controlled to obtain maximum cooling while ensuring complete evaporation of the liquid refrigerant within the evaporator. This is the job of a **thermostatic expansion valve (TEV or TXV)** or a fixed orifice tube. The TEV is mounted at the inlet to the evaporator and separates the high-pressure side of the system from the

low-pressure side. The TEV regulates the refrigerant flow to the evaporator by balancing the inlet flow to the outlet temperature.

Like the TEV, the **orifice tube** is the dividing point between the high- and low-pressure sides of the system. However, its metering or flow rate control does not depend on comparing evaporator pressure and temperature. It is a fixed orifice. The flow rate is determined by pressure difference across the orifice and by the additional cooling of the refrigerant in the bottom of the condenser after it has changed from vapor to liquid.

Evaporator The **evaporator**, like the condenser, consists of a refrigerant coil mounted in a series of thin cooling fins. The evaporator is usually located beneath the dashboard or instrument panel.

The low-pressure, low-temperature liquid refrigerant from the TEV or orifice tube enters the evaporator as a spray. The heat at the evaporator causes the refrigerant to boil and change into a vapor. The transfer of heat from the evaporator to the refrigerant causes the evaporator to get cold. Because hot air always moves toward cold air, the hot air from inside the vehicle moves across the evaporator. As the process of heat loss from the air to the evaporator core surface is taking place, any moisture in the air condenses on the outside of the evaporator core and is drained off as water. This dehumidification of air adds to passenger comfort.

Refrigerant Lines There are three major refrigerant lines. Suction lines are located between the outlet side of the evaporator and the inlet side or suction side of the compressor. They carry the low-pressure, low-temperature vapor to the compressor. The discharge or high-pressure line connects the compressor to the condenser. The liquid lines connect the condenser to the receiver/dryer and the receiver/dryer to the inlet side of the expansion valve. Through these lines, the refrigerant travels in its path from a gas state (compressor outlet) to a liquid state (condenser outlet) and then to the inlet side of the expansion valve, where it vaporizes at the evaporator.

DRIVETRAIN

The **drivetrain** is made up of all components that transfer power from the engine to the driving wheels of the vehicle. The exact components used in a vehicle's drivetrain depend on whether the vehicle is equipped with rear-wheel drive, front-wheel drive, or four-wheel drive.

Today, most cars are front-wheel drive (FWD). Some larger luxury and performance cars are

rear-wheel drive (RWD). Most pickup trucks, minivans, and SUVs are also RWD vehicles. Power flow in an RWD vehicle passes through the **clutch** or **torque converter**, manual or automatic transmission, and the driveline (drive shaft assembly). Then it goes through the rear differential, the rear-driving axles, and onto the rear wheels.

Power flow through the drivetrain of FWD vehicles passes through the clutch or torque converter, then moves through a front differential, the driving axles, and onto the front wheels.

Four-wheel-drive (4WD) or all-wheel-drive (AWD) vehicles combine features of both rear- and front-wheel-drive systems so that power can be delivered to all wheels either on a permanent or on-demand basis. Typically if a truck, pickup or SUV, has 4WD, the system is based on an RWD and a front drive axle is added. When a car has AWD or 4WD, the drivetrain is a modified FWD system. Modifications include a rear drive axle and an assembly that transfers some of the power to the rear axle.

Clutch

A clutch is used with manual transmissions/transaxles. It mechanically connects the engine's flywheel to the transmission/transaxle input shaft (**Figure 3-30**). This is accomplished by a special friction plate that is splined to the input shaft of the transmission. When

the clutch is engaged, the friction plate contacts the flywheel and transfers power to the input shaft.

When stopping, starting, and shifting from one gear to the next, the clutch is disengaged by pushing down on the clutch pedal. This moves the clutch plate away from the flywheel, stopping power flow to the transmission. The driver can then shift gears without damaging the transmission or transaxle. Releasing the clutch pedal reengages the clutch and allows power to flow from the engine to the transmission.

Manual Transmission

A manual or standard transmission is one in which the driver manually selects the gear of choice. Proper gear selection allows for good driveability and requires some driver education.

Whenever two or three gears have their teeth meshed together, a gearset is formed. The movement of one gear in the set will cause the others to move. If any of the gears in the set are a different size than the others, the gears will move at different speeds. The size ratio of a gearset is called the **gear ratio** of that gearset.

A manual transmission houses a number of individual gearsets, which produce different gear ratios (**Figure 3-31**). The driver selects the desired operating gear or gear ratio. A typical manual transmission has four or five forward gear ratios, neutral, and reverse.

Figure 3-30 The major components of a clutch assembly for a manual transmission.

Figure 3-31 A typical manual transaxle. Courtesy of Chrysler LLC

Automatic Transmission

An automatic transmission does not need a clutch pedal and shifts through the forward gears without the control of the driver. Instead of a clutch, it uses a torque converter to transfer power from the engine's flywheel to the transmission input shaft. The torque converter allows for smooth transfer of power at all engine speeds (**Figure 3-32**).

Shifting in an automatic transmission is controlled by a hydraulic and/or electronic control system. In a hydraulic system, an intricate network of valves and other components use hydraulic pressure to control the operation of planetary gearsets. These gearsets provide the three or four forward speeds, neutral, park, and reverse gears normally found in automatic transmissions. Newer electronic shifting systems use electric solenoids to control shifting mechanisms.

Figure 3-32 A cutaway of a six-speed automatic transmission shown with the torque converter in the housing. Courtesy of BMW of North America, LLC

Electronic shifting is precise and can be varied to suit certain operating conditions. All automatic transmission-equipped vehicles with OBD II have electronic shifting.

Driveline

Drivelines are used on RWD vehicles and 4WD vehicles. They connect the output shaft of the transmission to the gearing in the rear axle housing. They are also used to connect the output shaft to the front and rear drive axles on a 4WD vehicle.

A driveline consists of a hollow drive or propeller shaft that is connected to the transmission and drive axle differential by universal joints (U-joints). These U-joints allow the drive shaft to move with movement of the rear suspension, preventing damage to the shaft.

Differential

On RWD vehicles, the drive shaft turns perpendicular to the forward motion of the vehicle. The differential gearing in the rear axle housing is designed to turn the direction of the power so that it can be used to drive the wheels of the vehicle. The power flows into the **differential**, where it changes direction, then flows to the rear axles and wheels (**Figure 3-33**).

The gearing in the differential also multiplies the torque it receives from the drive shaft by providing a final gear reduction. Also, it divides the torque between the left and right driving axles and wheels so that a differential wheel speed is possible. This means one wheel can turn faster than the other when going around turns.

Driving Axles

Driving axles are solid steel shafts that transfer the torque from the differential to the driving wheels. A separate axle shaft is used for each driving wheel. In an RWD vehicle, the driving axles are part of the

Figure 3-33 The driveline connects the output from the transmission to the differential unit and drive axles. Courtesy of BMW of North America, LLC

differential and are enclosed in an axle housing that protects and supports these parts. Some rear drive axle units are mounted to an independent suspension and the drive axle assembly is similar to that of a FWD vehicle.

Each drive axle is connected to the side gears in the differential. The inner ends of the axles are splined to fit into the side gears. As the side gears are turned, the axles to which they are splined turn at the same speed.

The drive wheels are attached to the outer ends of the axles. The outer end of each axle has a flange mounted to it. A **flange** is a rim for attaching one part to another part. The flange, fitted with studs, at the end of an axle holds the wheel in place. **Studs** are threaded shafts, resembling bolts without heads. One end of the stud is screwed or pressed into the flange. The wheel fits over the studs, and a nut, called the **lug nut**, is tightened over the open end of the stud. This holds the wheel in place.

The differential carrier supports the inner end of each axle. A bearing inside the axle housing supports the outer end of the axle shaft. This bearing, called the axle bearing, allows the axle to rotate smoothly inside the axle housing.

Transaxle

A **transaxle** is used on FWD vehicles. It is made up of a transmission and differential housed in a single unit (Figure 3-34). The gearsets in the transaxle provide the required gear ratios and direct the power flow into the differential. The differential gearing provides the final gear reduction and splits the power flow between the left and right drive axles.

Figure 3-34 A cutaway of an automatic transaxle. Courtesy of Chrysler LLC

The drive axles extend from the sides of the transaxle. The outer ends of the axles are fitted to the hubs of the drive wheels. **Constant velocity (CV) joints** mounted on each end of the drive axles allow for changes in length and angle without affecting the power flow to the wheels.

Four-Wheel-Drive System

4WD or AWD vehicles combine the features of RWD transmissions and FWD transaxles. Additional **transfer case** gearing splits the power flow between a differential driving the front wheels and a rear differential that drives the rear wheels. This transfer case can be a housing bolted directly to the transmission/transaxle, or it can be a separate housing mounted somewhere in the driveline. Most RWD-based 4WD vehicles have a drive shaft connecting the output of the transmission to the rear axle and another connecting the output of the transfer case to the front drive axle. Typically, AWD cars have a center differential, which splits the torque between the front and rear drive axles.

RUNNING GEAR

The **running gear** of a vehicle includes those parts that are used to control the vehicle, which includes the wheels and tires and the suspension, steering, and brake systems.

Suspension System

The suspension system (Figure 3-35) includes such components as the springs, shock absorbers, MacPherson struts, torsion bars, axles, and connecting linkages. These components are designed to support the body and frame, the engine, and the drivelines. Without these systems, the comfort and ease of driving the vehicle would be reduced.

Springs or **torsion bars** are used to support the axles of the vehicle. The two types of springs commonly used are the coil spring and the leaf spring. Torsion bars are also used and are long spring steel rods. One end of the rod is connected to the frame, whereas the other end is connected to the movable parts of the axles. As the axles move up and down, the rod twists and acts as a spring.

Shock absorbers dampen the upward and downward movement of the springs. This is necessary to limit the car's reaction to a bump in the road.

Steering System

The steering system allows the driver to control the direction of the vehicle. It includes the steering wheel, steering gear, steering shaft, and steering linkage.

Two basic types of steering systems are used today: the **rack-and-pinion** and **recirculating ball** systems

Figure 3-35 A strut assembly of a typical suspension system. *Courtesy of Ford Motor Company*

(Figure 3-36). The rack-and-pinion system is commonly used in passenger cars. The recirculating ball system is normally used only on pickup trucks, SUVs, and full-size luxury cars.

Steering gears provide a gear reduction to make changing the direction of the wheels easier. On most vehicles, the steering gear is also power assisted to ease the effort of turning the wheels. In a power-assisted system, a pump provides hydraulic fluid under pressure to the steering gear. Pressurized fluid is directed to one side or the other of the steering gear to make it easier to turn the wheels.

Some vehicles are equipped with speed-sensitive power steering systems. These change the amount of power assist according to vehicle speed. Power assist is the greatest when the vehicle is moving slowly and decreases as speed increases.

Brakes

Obviously, the brake system is used to slow down and stop a vehicle (Figure 3-37). Brakes, located at each wheel, use friction to slow and stop a vehicle.

The brakes are activated when the driver presses down on the brake pedal. The brake pedal is connected to a plunger in a **master cylinder**, which is filled with hydraulic fluid. As pressure is put on the brake pedal, a force is applied to the hydraulic fluid in the master cylinder. This force is increased by the

(B)

Figure 3-37 A typical hydraulic brake system with disc brakes at the front and rear wheels.

master cylinder and transferred through brake hoses and lines to the four brake assemblies.

Two types of brakes are used—**disc brakes** and **drum brakes**. Many vehicles use a combination of the two types: disc brakes at the front wheels (Figure 3-38) and drum brakes at the rear wheels; others have disc brakes at all wheels.

Most vehicles have power-assisted brakes. Many vehicles use a vacuum **brake booster** to increase the

Figure 3-38 A disc brake unit with a wheel speed sensor for ABS. Courtesy of Chrysler LLC

pressure applied to the plunger in the master cylinder. Others use hydraulic pressure from the power steering pump to increase the pressure on the brake fluid. Both of these systems lessen the amount of pressure that must be applied to the brake pedal and increase the responsiveness of the brake system.

Nearly all late-model vehicles have an **antilock brake system (ABS)**. The purpose of ABS is to prevent skidding during hard braking to give the driver control of the vehicle during hard stops.

Wheels and Tires

The only contact a vehicle has with the road is through its tires and wheels. Tires are filled with air and made of forms of rubber and other materials to give them strength. Wheels are made of metal and are bolted to the axles or spindles (**Figure 3-39**). Wheels hold the

Figure 3-39 An alloy wheel with high-performance tires.

tires in place. Wheels and tires come in many different sizes. Their sizes must be matched to one another and to the vehicle.

HYBRID VEHICLES

A **hybrid electric vehicle (HEV)** uses one or more electric motors and an engine to propel the vehicle (**Figure 3-40**). Depending on the design of the system, the engine may move the vehicle by itself, assist the electric motor while it is moving the vehicle, or it may drive a generator to charge the vehicle's batteries. The electric motor may power the vehicle by itself or assist the engine while it is propelling the vehicle. Many hybrids rely exclusively on the electric motor(s) during slow speed operation, the engine at higher speeds, and both during some certain driving conditions. Complex electronic controls monitor the operation of the vehicle. Based on the current operating conditions, electronics control the engine, electric motor, and generator.

A hybrid's electric motor is powered by high-voltage batteries, which are recharged by a generator driven by the engine and through regenerative braking. **Regenerative braking** is the process by which a vehicle's kinetic energy can be captured while it is decelerating and braking. The electric drive motors become generators driven by the vehicle's wheels. These generators take the kinetic energy, or the energy of the moving vehicle, and changes it into energy that charges the batteries. The magnetic forces inside the

Figure 3-40 The electric motor in this hybrid arrangement fits between the engine and the transmission. Courtesy of American Honda Motor Co., Inc.

generator cause the drive wheels to slow down. A conventional brake system brings the vehicle to a safe stop.

The engines used in hybrids are specially designed for the vehicle and electric assist. Therefore, they can operate more efficiently, resulting in very good fuel economy and very low tailpipe emissions. HEVs can provide the same performance, if not better, as a comparable vehicle equipped with a larger engine.

There are primarily two types of hybrids: the parallel and the series designs. A parallel HEV uses either the electric motor or the gas engine to propel the vehicle, or both. The engine in a true series HEV is used only to drive the generator that keeps the batteries charged. The vehicle is powered only by the electric motor(s). Most current HEVs are considered as having a series/parallel configuration because they have the features of both designs.

Although most current hybrids are focused on fuel economy, the same ideas can be used to create high-performance vehicles. Hybrid technology is also influencing off-the-road performance. By using individual motors at the front and rear drive axles, additional power can be applied to certain drive wheels when needed.

KEY TERMS

AC generator	Disc brakes
Antilock brake system (ABS)	Distributor
Brake booster	Drivetrain
Carbon monoxide (CO)	Drum brakes
Clutch	Engine block
Combustion	Evaporator
Combustion chamber	Exhaust gas recirculation (EGR)
Compressor	Exhaust manifold
Condenser	Flange
Connecting rod	Friction
Constant velocity (CV) joint	Gear ratio
Convertible	Hatchback
Corporate Average Fuel Economy (CAFE)	Hybrid electric vehicle (HEV)
Cradle	Hydrocarbons (HC)
Crankshaft	Hydroforming
Crankshaft position sensor	Ignition coil
Crossover vehicles	Intake manifold
Cylinder block	Liftback
Cylinder head	Lug nut
Differential	Manifold
	Master cylinder
	Oil pan
	Oil sump

SUMMARY

- Dramatic changes to the automobile have occurred over the last 40 years, including the addition of emission control systems, more fuel-efficient and cleaner-burning engines, and lighter body weight.
- In addition to being lighter than body-over-frame vehicles, unibodies offer better occupant protection by distributing impact forces throughout the vehicle.
- Today's computerized engine control systems regulate such things as air and fuel delivery, ignition timing, and emissions. The result is an increase in overall efficiency.
- All automotive engines are classified as internal combustion, because the burning of the fuel and air occurs inside the engine. Diesel engines share the same major parts as gasoline engines, but they do not use a spark to ignite the air-fuel mixture.
- The cooling system maintains proper engine temperatures. Liquid cooling is more efficient than air cooling and it is more commonly used.
- The lubrication system distributes motor oil throughout the engine. This system also contains the oil filter necessary to remove dirt and other foreign matter from the oil.
- The fuel system is responsible not only for fuel storage and delivery, but also for atomizing and mixing it with the air in the correct proportion.

- The exhaust system has three primary purposes: to channel toxic exhaust away from the passenger compartment, to quiet the exhaust pulses, and to burn the emissions in the exhaust.
- The electrical system of an automobile includes the ignition, starting, charging, and lighting systems. Electronic engine controls regulate these systems very accurately through the use of computers.
- Modern automatic transmissions use a computer to match the demand for acceleration with engine speed, wheel speed, and load conditions. It then chooses the proper gear ratio and, if necessary, initiates a gear change.
- The running gear is critical to controlling the vehicle. It consists of the suspension system, braking system, steering system, and wheels and tires.
- Hybrid electric vehicles have an internal combustion engine and an electrical motor that are used to propel the vehicle together or separately.

REVIEW QUESTIONS

- Under the CAFE standards, for what are vehicles tested?
- Define internal combustion.
- In addition to the battery, what does the charging system include?
- Which of the following is *not* a typical emission control system?
 - EGR
 - PCV
 - EPA
 - air injection
- Automatic transmissions use a _____ instead of a clutch to transfer power from the flywheel to the transmission's input shaft.
 - differential
 - U-joint
 - torque converter
 - constant velocity joint
- Which of the following is *not* one of the strokes of a four-cycle engine?
 - compression
 - exhaust
 - intake
 - combustion
- Technician A says that the PCV system is designed to limit CO emissions. Technician B says that catalytic converters reduce HC emissions at the tailpipe. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- Which type of engine is classified as internal combustion?
 - gasoline
 - diesel
 - both a and b
 - neither a nor b
- What does the valve train do?
 - It delivers fuel to a device that controls the amount of fuel going to the engine.
 - It houses the major parts of the engine.
 - It converts reciprocating motion to rotary motion.
 - It opens and closes the intake and exhaust ports of each cylinder.
- Technician A says that liquid cooling an engine maintains a constant operating temperature. Technician B says that oil is circulated through the cooling system to remove heat from the engine's parts. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- An engine will not start and no spark is found at the spark plugs when the engine is turned over by the starter. Technician A says that the problem is probably the battery. Technician B says that the ignition system is most likely at fault. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- Which emission control system introduces exhaust gases into the intake air to reduce the formation of NO_x in the combustion chamber?
 - evaporative emission controls
 - exhaust gas recirculation
 - air injection
 - early fuel evaporation
- Technician A says that many vehicles use an AC generator as the charging unit. Technician B says that many vehicles use an alternator as the charging unit. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- Technician A says that a transaxle delivers torque to the front and the rear drive axles. Technician B says that a transaxle is most commonly found in 4WD pickups and SUVs. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B

15. Which of the following is *not* part of the running gear?
 - a. differential
 - b. steering
 - c. suspension
 - d. brakes
16. Which of the following statements about unibody construction is *not* true?
 - a. A unibody is a stressed hull structure in which each of the body parts supplies structural support and strength to the entire vehicle.
 - b. Unibody vehicles tend to be tightly constructed because the major parts are all welded together.
 - c. All unibodies are constructed from steel.
 - d. Most front-wheel-drive unibody vehicles have a cradle or partial frame.
17. A four-cylinder engine can have _____ ignition coils.
 - a. one
 - b. two
 - c. four
 - d. one, two, or four
18. Which of the following components are used to dampen the upward and downward movement of a vehicle's springs?
 - a. torsion bars
 - b. shock absorbers
 - c. constant velocity joints
 - d. connecting linkages
19. *True or False?* A hybrid electric vehicle uses regenerative braking to safely stop.
20. What two major engine components work together to change the reciprocating motion of the pistons into a rotary motion?
 - a. crankshaft and connecting rod
 - b. camshaft and crankshaft
 - c. camshaft and connecting rod
 - d. crankshaft and valve train
21. Technician A says that an air-conditioning system removes heat from inside the vehicle. Technician B says that the heating system adds heat to the inside of the vehicle. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
22. The boiling point of the coolant in an engine's cooling system is raised by the _____.
 - a. thermostat
 - b. pressure cap
 - c. radiator
 - d. water pump
23. While discussing the operation of air-conditioning systems: Technician A says that in order for the refrigerant to release heat, it must be at a low temperature and pressure. Technician B says that in order for the refrigerant to absorb heat, it must be at a high temperature and pressure. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
24. While discussing HEVs: Technician A says that in a series hybrid, the engine is only used to power a generator to recharge the batteries. Technician B says that in a parallel hybrid, the engine always supplies some of the power to move the vehicle. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
25. Which of the following is *not* accomplished by the fuel and air system of a gasoline engine?
 - a. stores the fuel for later use
 - b. collects and cleans the outside air
 - c. delivers fuel to a device that will control the amount of fuel going to the engine
 - d. keeps the fuel and air ratio constant regardless of the conditions under which the engine is operating

HAND TOOLS AND SHOP EQUIPMENT

CHAPTER

4

OBJECTIVES

- List the basic units of measure for length, volume, and mass in the two measuring systems.
- Describe the different types of fasteners used in the automotive industry.
- List the various mechanical measuring tools used in the automotive shop.
- Describe the proper procedure for measuring with a micrometer.
- List some of the hand tools used in auto repair.
- List the common types of shop equipment and state their purpose.
- Describe the use of common pneumatic, electrical, and hydraulic power tools found in an automotive service department.
- Describe the different sources for service information that are available to technicians.

Repairing the modern automobile requires the use of various tools. Many of these tools are common hand and power tools used every day by a technician. Other tools are very specialized and are only for specific repairs on specific systems and/or vehicles. This chapter presents some of the more commonly used hand and power tools with which every technician must be familiar. Because units of measurement play such an important part in tool selection and in diagnosing automotive problems, this chapter begins with a presentation of measuring systems. Prior to the discussion on tools, there is a discussion on another topic that relates very much to measuring systems—fasteners.

MEASURING SYSTEMS

Two systems of weights and measures exist side by side in the United States—the Imperial or U.S. customary system and the international or metric system.

The basic unit of linear measurement in the Imperial system is the inch. The basic unit of linear measurement in the metric system is the meter. The meter is easily broken down into smaller units, such as the centimeter ($\frac{1}{100}$ meter) and millimeter ($\frac{1}{1,000}$ meter).

All units of measurement in the metric system are related to each other by a factor of 10. Every metric unit can be multiplied or divided by the factor of 10 to get larger units (multiples) or smaller units (submul-

Figure 4-1 A meter stick has 1,000 increments known as millimeters and is slightly longer than a yardstick.

tiples). This makes the metric system much easier to use, with less chance of math errors than when using the Imperial system (**Figure 4-1**).

The United States passed the Metric Conversion Act in 1975 in an attempt to get American industry and the general public to use the metric system, as the rest of the world does. While the general public has been slow to drop the customary measuring system of inches, gallons, and pounds, many industries, led by the automotive industry, have now adopted the metric system for the most part.

Nearly all vehicles are now built to metric standards. Technicians must be able to measure and work with both systems of measurement. The following are some common equivalents in the two systems:

Linear Measurements

1 meter (m) = 39.37 inches (in.)

1 centimeter (cm) = 0.3937 inch

1 millimeter (mm) = 0.03937 inch

1 inch = 2.54 centimeters
 1 inch = 25.4 millimeters
 1 mile = 1.6093 kilometers

Square Measurements

1 square inch = 6.452 square centimeters
 1 square centimeter = 0.155 square inch

Volume Measurements

1 cubic inch = 16.387 cubic centimeters
 1,000 cubic centimeters = 1 liter (l)
 1 liter (l) = 61.02 cubic inches
 1 gallon = 3.7854 liters

Weight Measurements

1 ounce = 28.3495 grams
 1 pound = 453.59 grams
 1,000 grams = 1 kilogram
 1 kilogram = 2.2046 pounds

Temperature Measurements

1°Fahrenheit (F) = $\frac{5}{9}C + 32^\circ$
 1°Celsius (C) = $\frac{5}{9}(F - 32^\circ)$

Pressure Measurements

1 pound per square inch (psi) = 0.07031 kilogram (kg) per square centimeter
 1 kilogram per square centimeter = 14.22334 pounds per square inch
 1 bar = 14.504 pounds per square inch
 1 pound per square inch = 0.06895 bar
 1 atmosphere = 14.7 pounds per square inch

Torque Measurements

10 foot-pounds (ft.-lb) = 13.558 Newton meters (N-m)
 1 N-m = 0.7375 ft.-lb
 1 ft.-lb = 0.138 m kg
 1 cm kg = 7.233 ft.-lb
 10 cm kg = 0.98 N-m

FASTENERS

Fasteners are used to secure or hold different parts together or to mount a component. Many types and sizes of fasteners are used in automobiles. Each fastener is designed for a specific purpose and condition. The most commonly used is the threaded fastener.

Figure 4-2 Common automotive threaded fasteners.

Threaded fasteners include bolts, nuts, screws, and similar items that allow for easy removal and installation of parts (**Figure 4-2**).

The threads can be cut or rolled into the fastener. Rolled threads are 30% stronger than cut threads. They also offer better fatigue resistance because there are no sharp notches to create stress points. There are four classifications for the threads of Imperial fasteners: Unified National Coarse (UNC), Unified National Fine (UNF), Unified National Extrafine (UNEF), and Unified National Pipe Thread (UNPT or NPT). Metric fasteners are also available in fine and coarse threads.

NPT is the standard thread design for joining pipes and fittings. There are two basic designs: tapered and straight cut threads. Straight cut pipe thread is used to join pipes but it does not provide a good seal at the joining point. Tapered pipe threads provide a good seal because the internal and external threads compress against each other as the joint is tightened. Most often a sealant is used on pipe threads to provide a better seal. Pipe threads are commonly used at the ends of hoses and lines that carry a liquid or gas (**Figure 4-3**).

Coarse (UNC) threads are used for general-purpose work, especially where rapid assembly and disassembly are required. Fine threads (UNF) are used where greater holding force is necessary. They are also used where greater vibration resistance is desired.

Figure 4-3 Various sizes of pipe fittings used with lines and hoses.

Figure 4-4 Basic terminology for bolt identification.

Bolts

Bolts have a head on one end and threads on the other. They are identified by their head size, shank (shoulder) diameter, thread pitch, length (**Figure 4-4**), and grade. The threads of a bolt travel from below the shank to the end of the bolt.

The **bolt head** is used to loosen and tighten the bolt; a socket or wrench fits over the head and is used to screw the bolt in or out. The size of the bolt head varies with the bolt’s diameter and is available in Imperial and metric wrench sizes. Many confuse the size of the head with the size of the bolt. The size of a bolt is the diameter of its shank. **Table 4-1** lists the most common bolt head sizes.

Bolt diameter is the measurement across the diameter of the threaded area or **bolt shank**. The length of a bolt is measured from the bottom surface of the head to the end of the threads.

TABLE 4-1 STANDARD BOLT HEAD SIZES

*This does not suggest equivalency.

The **thread pitch** of a bolt in the Imperial system is the number of threads that are in 1 inch of the threaded length and is expressed in number of threads per inch. A UNF bolt with a 3/8-inch diameter is marked as a 3/8 × 24 bolt. It has 24 threads per inch. Likewise a 3/8-inch UNC bolt is called a 3/8 × 16 bolt.

The distance, in millimeters, between two adjacent threads determines the thread pitch in the metric system. This distance will vary between 1.0 and 2.0 and depends on the diameter of the bolt. The lower the number, the closer the threads are placed and the finer the threads are.

The bolt’s tensile strength, or grade, is the amount of stress or stretch it is able to withstand before it breaks. The material that the bolt is made of and the diameter of the bolt determine its grade. In the Imperial system, the tensile strength of a bolt is identified by the number of radial lines (**grade marks**) on the

Customary (inch) bolts—identification marks correspond to bolt strength—increasing numbers represent increasing strength.

Metric bolts—identification class numbers correspond to bolt strength—increasing numbers represent increasing strength.

Figure 4-5 Bolt grade markings.

bolt’s head. More lines mean higher tensile strength (**Figure 4-5**). Count the number of lines and add 2 to determine the grade of a bolt.

On metric bolts, a property class number on the bolt head identifies its grade. The property class is expressed with two numbers. The first represents the tensile strength of the bolt. The higher the number, the greater the tensile strength. The second is a percentage rating of the bolt’s yield strength. This denotes how much stress the bolt can take before it is not able to return to its original shape. For example, a 10.9 bolt has a tensile strength of 1,000 MPa (145,000 psi) and a yield strength of 900 MPa (90% of 1,000). A 10.9 metric bolt is similar in strength to a grade 8 bolt.

Nuts are graded to match their respective bolts (**Table 4-2**); a grade 8 nut must be used with a grade 8 bolt. If a grade 5 nut is used, a grade 5 connection would result.

Figure 4-6 Bolt fillet detail.

SHOP TALK

Bolt heads can pop off because of **fillet** damage. The fillet is the slightly curved area where the shank flows into the bolt head (**Figure 4-6**). Scratches in this area introduce stress to the bolt head, causing failure. Replace all bolts that are damaged.

Tightening Bolts Any fastener is near worthless if it is not as tight as it should be. When a bolt is properly tightened, it will be “spring loaded” against the part it is holding. This spring effect is caused by the stretch of the bolt. Normally a properly tightened bolt is stretched to 70% of its elastic limit. The elastic limit of a bolt is that point of stretch from which the bolt will

TABLE 4-2 STANDARD NUT STRENGTH MARKINGS			
Inch System		Metric System	
Grade	Identification	Class	Identification
Hex Nut Grade 5	 3 Dots	Hex Nut Property Class 9	 Arabic 9
Hex Nut Grade 8	 6 Dots	Hex Nut Property Class 10	 Arabic 10
Increasing dots represent increasing strength.		Can also have blue finish or paint dab on hex flat. Increasing numbers represent increasing strength.	

Figure 4-7 A comparison of a stretched and an unstretched bolt.

not return to its original shape when it is loosened. Not only will an overtightened or stretched bolt not have sufficient clamping force, it also will have distorted threads. The stretched threads will make it more difficult to screw and unscrew the bolt or a nut on the bolt (**Figure 4-7**).

Fatigue breaks are the most common causes of bolt failure. A bolt becomes fatigued when it is able to move in its bore due to being undertightened.

Washers

Many different types of washers are used with fasteners. Flat washers are used to spread out the load of tightening a nut or bolt. This stops the bolt head or nut from digging into the surface as it is tightened. Also place flat washers with their rounded, punched side against the bolt head. Soft flat washers, sometimes called compression washers, are also used to spread the load of tightening and help seal one component to another. Copper washers are often used

with oil pan bolts to help seal the pan to the engine block. Grade 8 and other critical applications require the use of fully hardened flat washers. These will not dish out when tightened like soft washers.

Lock washers are used to lock the head of a bolt or nut to the workpiece to keep them from coming loose and to prevent damage to softer metal parts.

Other Common Fasteners

The use of other fastener designs depends on the purpose of the fastener. Some of the more commonly used fasteners are described here.

Nuts Nuts are used with other threaded fasteners. Many different designs of nuts are found on today's cars (**Figure 4-8**). The most common one is the hex nut, which is used with studs and bolts and tightened with a wrench.

Locknuts are often used in places where vibration may tend to loosen a nut. Locking nuts are standard nuts with nylon inserted into a section of the threads. The nylon cushions the vibrations.

Studs Studs are rods with threads on both ends. Most often, the threads on one end are coarse while the threads on the other end are fine. One end of the stud is screwed into a threaded bore. A bore in the part that will be mounted by the stud is fit over the stud and held in place with a nut that is screwed onto the stud. Studs are used when the clamping pressures of a fine thread are needed and a bolt will not work. If the stud is being screwed into soft (such as aluminum) or granular (such as cast iron) material, that end of the stud will have coarse threads. The opposite end will have fine threads. As a result, a coarse thread is used to hold the stud in a component and a fine-threaded

Figure 4-8 Many different types of nuts are used on automobiles. Each type has a specific purpose.

nut is used to clamp the other part to it. This provides for the clamping force of fine threads and the holding power of coarse threads.

Cap Screws Cap screws are similar to bolts, but they do not have a shoulder. The threads travel from the head to the end of the screw. Never use a cap screw in place of a bolt.

Setscrews Setscrews are used to prevent rotary motion between two parts, such as a pulley and shaft. Setscrews have a square head and are moved with a wrench, or they are headless and require an Allen wrench or screwdriver to move them.

Machine Screws The length of machine screws is entirely threaded. These screws have a head on one end and a flat bottom on the other. Machine screws are used to mount one component to another that has a threaded bore. They are also used with a nut to hold parts together. Machine screws can have a round, flat, Torx, oval, or fillister head.

Self-Tapping Screws Self-tapping screws are used to fasten sheet metal parts or to join together light metal with wood or plastic parts. These screws form their own threads in the material into which they are screwed.

Thread Lubricants and Sealants

It is often recommended that the threads of a bolt or stud be coated with a sealant or lubricant. The most commonly used lubricant is antiseize compound. Antiseize compound is used where a bolt might become difficult to remove after a period of time—for example, in an aluminum engine block. The amount of torque required to properly tighten a bolt treated with antiseize compound should be reduced. Thread lubricants may also cause hydrostatic lock; oil can be trapped in a blind hole. When the bolt contacts the oil, it cannot compress it; therefore, the bolt cannot be properly tightened or fully seated.

Thread sealants are used on bolts that are tightened into an oil cavity or coolant passage. The sealant prevents the liquid from seeping past the threads. Teflon tape is often used as a sealant. Another commonly used thread chemical, called threadlocker (Figure 4-9), prevents a bolt from working loose as the engine or another part vibrates.

Thread Pitch Gauge

The use of a **thread pitch gauge** provides a quick and accurate way to check the thread pitch of a fastener. The leaves of the tool are marked with the various pitches. To check the pitch of threads, simply match

Figure 4-9 A container of threadlocker. Courtesy of Permatex, Inc.

the teeth of the gauge with the threads of the fastener. Then read the pitch from the leaf. Thread pitch gauges are available for the various threads used by the automotive industry.

Taps and Dies

The hand **tap** is a small tool used for hand cutting internal threads (Figure 4-10). An internal thread is cut on the inside of a part, such as a thread on the inside of a nut. Taps are also available that only clean and restore threads that were previously cut. Taps are selected by size and thread pitch. Photo Sequence 1 goes through the correct procedure for repairing damaged threads with a tap.

When tapping a bore, rotate the tap in a clockwise direction. Then, turn the tap counterclockwise about a quarter turn to break off any metal chips that may have accumulated in the threads. These small metal pieces can damage the threads as you continue to tap. These metal chips are gathered in the tap's flutes, which are recessed areas between the cutting teeth of the tap (Figure 4-11). After backing off the tap, continue rotating the tap clockwise. Remember

Figure 4-10 A tap and die set.

Figure 4-11 Metal chips are gathered into the flutes of a tap.

to back off the tap periodically and make sure all of the existing threads in the bore have been recut by the tap.

Hand-threading **dies** are the opposite of taps because they cut external (outside) threads on bolts, rods, and pipes rather than internal threads. Dies are

made in various sizes and shapes, depending on the particular work for which they are intended. Dies may be solid (fixed size), split on one side to permit adjustment, or have two halves held together in a collet that provides for individual adjustments. Dies fit into holders called die stocks.

Threaded Inserts

When the threads in a bore are excessively damaged, it is better to replace them than try to tap them. A thread insert can be used to restore the original threads. Inserts require drilling the bore to a larger diameter and tapping that bore to allow the insert to be screwed into it. The inner threaded diameter of the insert will provide fresh threads for the bolt (Figure 4-12).

Spark Plug Thread Repair Sometimes when spark plugs are removed from a cylinder head, the threads have traces of metal on them. This happens more often with aluminum heads. When this occurs, the spark plug bore must be corrected by installing thread inserts.

SHOP TALK

Never change spark plugs when the cylinder head is hot. The bores for the plugs can take on an oval shape as the cylinder head cools without spark plugs in the bores.

Figure 4-12 Using a threaded insert (heli-coil®) to repair damaged threads. Courtesy of Emhart Fastening Technologies

Repairing Damaged Threads with a Tap

P1-1 Using a thread pitch gauge, determine the thread size of the fastener that should fit into the damaged internal threads.

P1-2 Select the correct size and type of tap for the threads and bore to be repaired.

P1-3 Install the tap into a tap wrench.

P1-4 Start the tap squarely in the threaded hole using a machinist square as a guide.

P1-5 Rotate the tap clockwise into the bore until the tap has run through the entire length of the threads. While doing this, periodically turn the tap backward to clean the threads. This prevents breaking the tap.

P1-6 Drive the tap back out of the hole by turning it counterclockwise.

P1-7 Clean the metal chips left by the tap out of the hole.

P1-8 Inspect the threads left by the tap to be sure they are acceptable.

P1-9 Test the threads by threading the correct fastener into the threaded hole.

When installing spark plugs, if the plugs cannot be installed easily by hand, the threads in the cylinder head may need to be cleaned with a thread-chasing tap. There are special taps for spark plug bores, simply called **spark plug thread taps**. Be especially careful not to cross-thread the plugs when working with aluminum heads. Always tighten the plugs with a torque wrench and the correct spark plug socket, following the vehicle manufacturer's specifications. Also, when changing spark plugs in aluminum heads, the temperature of the heads should be ambient temperature before attempting to remove the plugs.

MEASURING TOOLS

Some service work, such as engine repair, requires very exact measurements, often in ten-thousandths (0.0001) of an inch or thousandths (0.001) of a millimeter. Accurate measurements with this kind of precision can only be made by using precise measuring devices.

Measuring tools are precise and delicate instruments. In fact, the more precise they are, the more delicate they are. They should be handled with great care. Never pry, strike, drop, or force these instruments. They may be permanently damaged.

Precision measuring instruments, especially micrometers, are extremely sensitive to rough handling. Clean them before and after every use. All measuring should be performed on parts that are at room temperature to eliminate the chance of measuring something that has contracted because it was cold or has expanded because it was hot.

SHOP TALK

Check measuring instruments regularly against known good equipment to ensure that they are operating properly and are capable of accurate measurement. Always refer to the appropriate material for the correct specifications before performing any service or diagnostic procedures. The close tolerances required for the proper operation of some automotive parts make using the correct specifications and taking accurate measurements very important. Even the slightest error in measurement can be critical to the durability and operation of an engine and other systems.

Machinist's Rule

The **machinist's rule** looks very much like an ordinary ruler. Each edge of this basic measuring tool is

Figure 4-13 Graduations on a typical machinist's rule.

divided into increments based on a different scale. As shown in **Figure 4-13**, a typical machinist's rule based on the Imperial system of measurement may have scales based on $\frac{1}{8}$ -, $\frac{1}{16}$ -, $\frac{1}{32}$ -, and $\frac{1}{64}$ -inch intervals. Of course, metric machinist rules are also available. Metric rules are usually divided into 0.5 mm and 1 mm increments.

Some machinist's rules may be based on decimal intervals. These are typically divided into $\frac{1}{10}$ -, $\frac{1}{50}$ -, and $\frac{1}{1,000}$ -inch increments. Decimal machinist's rules are very helpful when measuring dimensions specified in decimals; they make such measurements much easier.

Vernier Caliper

A **vernier caliper** is a measuring tool that can make inside, outside, or depth measurements. It is marked in both British Imperial and metric divisions called a vernier scale. A vernier scale consists of a stationary scale and a movable scale, in this case the vernier bar to the vernier plate. The length is read from the vernier scale.

A vernier caliper has a movable scale that is parallel to a fixed scale (**Figure 4-14**). These precision measuring instruments are capable of measuring outside and inside diameters and most will even measure depth. Vernier calipers are available in both Imperial and metric scales. The main scale of the caliper is divided into inches; most measure up to 6 inches. Each inch is divided into 10 parts, each equal to

Figure 4-14 A vernier caliper. Courtesy of Central Tools, Inc.

Figure 4-15 Each line of the main scale equals 0.025 inch.

0.100 inch. The area between the 0.100 marks is divided into four. Each of these divisions is equal to 0.025 inch (**Figure 4-15**).

The vernier scale has 25 divisions, each one representing 0.001 inch. Measurement readings are taken by combining the main and vernier scales. At all times, only one division line on the main scale will line up with a line on the vernier scale (**Figure 4-16**). This is the basis for accurate measurements.

To read the caliper, locate the line on the main scale that lines up with the zero (0) on the vernier scale. If the zero lined up with the 1 on the main scale, the reading would be 0.100 inch. If the zero on the vernier scale does not line up exactly with a line on the main scale, then look for a line on the vernier scale that does line up with a line on the main scale.

Dial Caliper

The **dial caliper** (**Figure 4-17**) is an easier-to-use version of the vernier caliper. Imperial calipers commonly measure dimensions from 0 to 6 inches (0 to 150 mm). Metric dial calipers typically measure from 0 to 150 mm in increments of 0.02 mm. The dial caliper features a depth scale, bar scale, dial indicator, inside measurement jaws, and outside measurement jaws.

The main scale of a British Imperial dial caliper is divided into one-tenth (0.1) inch graduations. The dial indicator is divided into one-thousandth (0.001)

$$\begin{array}{rcl} \text{Example: } & 0.100'' & \text{Main scale} \\ & 0.005'' & \text{Vernier} \\ \hline & 0.105'' & \text{Overall} \end{array}$$

$$\begin{array}{rcl} \text{Example: } & 4.000'' & \text{Main scale} \\ & 0.275'' & \text{Main scale} \\ & 0.012'' & \text{Vernier} \\ \hline & 4.287'' & \text{Overall} \end{array}$$

Figure 4-16 To get a final measurement, line up the vernier scale line that is exactly aligned with any line on the main scale.

Figure 4-17 A dial vernier caliper. Courtesy of Central Tools, Inc.

inch graduations. Therefore, one revolution of the dial indicator needle equals one-tenth inch on the bar scale.

A metric dial caliper is similar in appearance; however, the bar scale is divided into 2 mm increments. Additionally, on a metric dial caliper, one revolution of the dial indicator needle equals 2 mm.

Both English and metric dial calipers use a thumb-operated roll knob for fine adjustment. When you use a dial caliper, always move the measuring jaws

backward and forward to center the jaws on the object being measured. Make sure the caliper jaws lay flat on or around the object. If the jaws are tilted in any way, you will not obtain an accurate measurement.

Although dial calipers are precision measuring instruments, they are only accurate to plus or minus two-thousandths (± 0.002) of an inch. Micrometers are preferred when extremely precise measurements are desired.

Micrometers

The **micrometer** is used to measure linear outside and inside dimensions. Both outside and inside micrometers are calibrated and read in the same manner. Measurements on both are taken with the measuring points in contact with the surfaces being measured.

The major components and markings of a micrometer include the frame, anvil, spindle, locknut, sleeve, sleeve numbers, sleeve long line, thimble marks, thimble, and ratchet (**Figure 4-18**). Micrometers are calibrated in either inch or metric graduations and are available in a range of sizes. The proper procedure for measuring with an inch-graduated outside micrometer is outlined in Photo Sequence 2.

Most micrometers are designed to measure objects with accuracy to 0.001 (one-thousandth) inch. Micrometers are also available to measure in 0.0001 (ten-thousandths) of an inch. This type of micrometer should be used when the specifications call for this much accuracy. Digital micrometers are also available (**Figure 4-19**). These eliminate the need to do math and still receive a precise measurement.

Reading a Metric Outside Micrometer The metric micrometer is read in the same manner as the inch-

Figure 4-18 Major components of (A) an outside and (B) an inside micrometer.

Figure 4-19 A digital micrometer eliminates the need to do math.

graduated micrometer, except the graduations are expressed in the metric system of measurement. Readings are obtained as follows:

- Each number on the sleeve of the micrometer represents 5 millimeters (mm) or 0.005 meter (m) (**Figure 4-20A**).
- Each of the 10 equal spaces between each number, with index lines alternating above and below the horizontal line, represents 0.5 mm or five-tenths of a mm. One revolution of the thimble changes the reading one space on the sleeve scale or 0.5 mm (**Figure 4-20B**).

Figure 4-20 Reading a metric micrometer: (A) 10 mm plus (B) 0.5 mm plus (C) 0.01 mm equals 10.51 mm.

Using a Micrometer

P2-1 Micrometers can be used to measure the diameter of many different objects. By measuring the diameter of a valve stem in two places, the wear of the stem can be determined.

P2-2 Because the diameter of a valve stem is less than 1 inch, a 0-to-1-inch outside micrometer is used.

P2-3 The graduations on the sleeve each represent 0.025 inch. To read a measurement on a micrometer, begin by counting the visible lines on the sleeve and multiplying them by 0.025.

P2-4 The graduations on the thimble assembly define the area between the lines on the sleeve. The number indicated on the thimble is added to the measurement shown on the sleeve.

P2-5 A micrometer reading of 0.500 inch.

P2-6 A micrometer reading of 0.375 inch.

Using a Micrometer (*continued*)

P2-7 Normally, little stem wear is evident directly below the keeper grooves. To measure the diameter of the stem at that point, close the micrometer around the stem.

P2-8 To get an accurate reading, slowly close the micrometer until a slight drag is felt while passing the valve in and out of the micrometer.

P2-9 To prevent the reading from changing while you move the micrometer away from the stem, use your thumb to activate the lock lever.

P2-10 This reading (0.311 inch) represents the diameter of the valve stem at the top of the wear area.

P2-11 Some micrometers are able to measure in 0.0001 (ten-thousandths) of an inch. Use this type of micrometer if the specifications call for this much accuracy. Note that the exact diameter of the valve stem is 0.3112 inch.

P2-12 Most valve stem wear occurs above the valve head. The diameter here should also be measured. The difference between the diameter of the valve stem just below the keepers and just above the valve head represents the amount of valve stem wear.

Figure 4-21 The total reading on this micrometer is 7.28 mm.

- The beveled edge of the thimble is divided into 50 equal divisions with every fifth line numbered: 0, 5, 10, . . . 45. Since one complete revolution of the thimble advances the spindle 0.5 mm, each graduation on the thimble is equal to one hundredth of a millimeter (**Figure 4-20C**).
- As with the inch-graduated micrometer, the three separate readings are added together to obtain the total reading (**Figure 4-21**).

To measure small objects with an outside micrometer, open the tool and slip the object between the spindle and anvil. While holding the object against the anvil, turn the thimble with your thumb and forefinger until the spindle contacts the object. Use only enough pressure on the thimble to allow the object to just fit between the anvil and spindle. Slip the micrometer back and forth over the object until you feel a very light resistance, while at the same time rocking the tool from side to side to make certain the spindle cannot be closed any further (**Figure 4-22**). After your final adjustment, lock the micrometer and read the measurement.

Micrometers are available in different sizes. The size is dictated by the smallest to the largest measurement it can make. Examples of these sizes are the 0-to-1-inch, 1-to-2-inch, 2-to-3-inch, and 3-to-4-inch micrometers.

Reading an Inside Micrometer Inside micrometers are used to measure the inside diameter of a bore or hole. The tool is placed into the bore and extended until each end touches the bore's surface. If the bore is large, it might be necessary to use an extension rod to increase the micrometer's range. These extension rods come in various lengths.

To get a precise measurement, keep the anvil firmly against one side of the bore and rock the micrometer back and forth and side to side. This centers the micrometer in the bore. Make sure there is

Figure 4-22 Slip the micrometer over the object and rock it from side to side.

correct resistance on both ends of the tool before taking a reading.

Reading a Depth Micrometer A depth micrometer (**Figure 4-23**) is used to measure the distance between two parallel surfaces. It operates and is read in the

Figure 4-23 A depth micrometer. Courtesy of Central Tools, Inc.

same way as other micrometers. If a depth micrometer is used with a gauge bar, it is important to keep both the bar and the micrometer from rocking. Any movement of either part will result in an inaccurate measurement.

SHOP TALK

Measurements with any micrometer will be reliable only if the micrometer is calibrated correctly. To calibrate a micrometer, close the micrometer over a micrometer standard. If the reading differs from that of the standard, the micrometer should be adjusted according to the instructions provided by the tool manufacturer. Proper care of a micrometer is also important to ensure accurate measurements. This care includes:

- Always clean the micrometer before using it.
- Do not touch the measuring surfaces.
- Store the tool properly. The spindle face should not touch the anvil face; a change in temperature might spring the micrometer.
- Clean the micrometer after use. Wipe it clean of any oil, dirt, or dust using a lint-free cloth.
- Never use the tool as a clamp or tighten the jaws too tightly around an object.
- Do not drop the tool.
- Check the calibration weekly.

Telescoping Gauge

Telescoping gauges (Figure 4-24) are used for measuring bore diameters and other clearances. They

Figure 4-24 Parts of a telescoping gauge.

may also be called **snap gauges**. They are available in sizes ranging from fractions of an inch through 6 inches (150 mm). Each gauge consists of two telescoping plungers, a handle, and a lock screw. Snap gauges are normally used with an outside micrometer.

To use the telescoping gauge, insert it into the bore and loosen the lock screw. This will allow the plungers to snap against the bore. Once the plungers have expanded, tighten the lock screw. Then, remove the gauge and measure the expanse with a micrometer.

Small Hole Gauge

A small hole or **ball gauge** works just like a telescoping gauge. However, it is designed to be used on small bores. After it is placed into the bore and expanded, it is removed and measured with a micrometer (Figure 4-25). Like the telescoping gauge, the small hole gauge consists of a lock, a handle, and an expanding end. The end expands or retracts by turning the gauge handle.

Feeler Gauge

A **feeler gauge** is a thin strip of metal or plastic of known and closely controlled thickness. Several of these metal strips are often assembled together as a feeler gauge set that looks like a pocket knife (Figure 4-26). The desired thickness gauge can be pivoted away from others for convenient use. A steel feeler gauge pack usually contains strips or leaves of 0.002- to 0.010-inch thickness (in steps of 0.001 inch) and leaves of 0.012- to 0.024-inch thickness (in steps of 0.002 inch). Metric feeler gauges are also available.

A feeler gauge can be used by itself to measure piston ring side clearance, piston ring end gap, connecting rod side clearance, crankshaft end play, and other distances.

Round wire feeler gauges are often used to measure spark plug gap. The round gauges are designed to give a better feel for the fit of the gauge in the gap.

Straightedge

A **straightedge** is no more than a flat bar machined to be totally flat and straight, and to be effective it must be flat and straight. Any surface that should be flat can be checked with a straightedge and feeler gauge set. The straightedge is placed across and at angles on the surface. At any low points on the surface, a feeler gauge can be placed between the straightedge and the surface (Figure 4-27). The size gauge that fills in the gap indicates the amount of warpage or distortion.

Figure 4-25 Insert the ball gauge into the bore to be measured. Then expand it, lock it, and remove it. Now measure it with an outside micrometer. *Courtesy of Ford Motor Company*

Dial Indicator

The **dial indicator** (Figure 4-28) is calibrated in 0.001-inch (one-thousandth inch) increments. Metric dial indicators are also available. Both types are used to measure movement. Common uses of the dial indicator include measuring valve lift, journal concentricity, flywheel or brake rotor runout, gear backlash, and crankshaft end play. Dial indicators are available with various face markings and

Figure 4-26 Typical feeler gauge set.

Figure 4-27 Using a feeler gauge and precision straightedge to check for warpage.

Figure 4-28 A dial indicator with a highly adaptive holding fixture.

Figure 4-29 This dial indicator setup will measure the amount this axle can move in and out.

measurement ranges to accommodate many measuring tasks.

To use a dial indicator, position the indicator rod against the object to be measured. Then, push the indicator toward the work until the indicator needle travels far enough around the gauge face to permit movement to be read in either direction (**Figure 4-29**). Zero the indicator needle on the gauge. Always be sure the range of the dial indicator is sufficient to allow the amount of movement required by the measuring procedure. For example, never use a 1-inch indicator on a component that will move 2 inches.

HAND TOOLS

Most service procedures require the use of hand tools. Therefore, technicians need a wide assortment of these tools. Each has a specific job and should be used in a specific way. Most service departments and garages require their technicians to buy their own hand tools.

Wrenches

The word *wrench* means twist. A wrench is a tool for twisting and/or holding bolt heads or nuts. Nearly all bolt heads and nuts have six sides; the jaw of a wrench fits around these sides to turn the bolt or nut. All technicians should have a complete collection of **wrenches**. This includes both metric and SAE wrenches in a variety of sizes and styles (**Figure 4-30**). The width of the jaw opening determines its size. For example, a ½-inch wrench has a jaw opening (from face to face) of ½ inch. The size is actually slightly larger than its nominal size so the wrench fits around a nut or bolt head of equal size.

SHOP TALK

Metric and SAE wrenches are not interchangeable. For example, a ⅝-inch wrench is 0.02 inch larger than a 14-millimeter nut. If the ⅝-inch wrench is used to turn or hold a 14-millimeter nut, the wrench will probably slip. This may cause rounding of the points of the nut and possibly skinned knuckles as well.

The following is a brief discussion of the types of wrenches used by automotive technicians.

Open-End Wrench The jaws of the open-end wrench (**Figure 4-31**) allow the wrench to slide around two sides of a bolt or nut head where there might be insufficient clearance above or on one side of the nut to accept a box wrench.

Box-End Wrench The end of the box-end wrench is boxed or closed rather than open. The jaws of the wrench fit completely around a bolt or nut, gripping each point on the fastener. The box-end wrench is not likely to slip off a nut or bolt. It is safer than an open-end wrench. Box-end wrenches are available as 6 point and 12 point (**Figure 4-32**). The 6-point box end grips the screw more securely than a 12-point box-end wrench can and avoids damage to the bolt head.

Combination Wrench The combination wrench has an open-end jaw on one end and a box-end on the other. Both ends are the same size. Every auto technician should have two sets of wrenches: one for holding and one for turning. The combination wrench is probably the best choice for the second set. It can be used with either open-end or box-end wrench sets and can be used as an open-end or box-end wrench.

Flare Nut (Line) Wrenches Flare nut or line wrenches should be used to loosen or tighten brake line or tubing fittings. Using open-ended wrenches on these fittings tends to round the corners of the nut, which are typically made of soft metal and can distort easily. Flare nut wrenches surround the nut and provide a better grip on the fitting. They have a section cut out so that the wrench can be slipped around the brake or fuel line and dropped over the flare nut.

Allen Wrench Setscrews are used to fasten door handles, instrument panel knobs, engine parts, and even brake calipers. A set of fractional and metric hex head

Figure 4-30 A technician needs many different sets of wrenches. *Reproduced under license from Snap-on Incorporated. All of the marks are marks of their owners.*

wrenches, or Allen wrenches (**Figure 4-33**), should be in every technician's toolbox. An Allen wrench can be L-shaped or can be mounted in a socket driver and used with a ratchet.

Adjustable-End Wrench An adjustable-end wrench (commonly called a crescent wrench) has one fixed jaw and one movable jaw. The wrench opening can be adjusted by rotating a helical adjusting screw that

is mated to teeth in the lower jaw. Because this type of wrench does not firmly grip a bolt's head, it is likely to slip. Adjustable wrenches should be used carefully and *only* when it is absolutely necessary. Be sure to put all of the turning pressure on the fixed jaw.

Sockets and Ratchets

A set of Imperial and metric sockets combined with a ratchet handle and a few extensions should be

Figure 4-31 An open-end wrench grips only two sides of a fastener.

Figure 4-32 Six-point and twelve-point box-end wrenches are available.

included in your tool set. The ratchet allows you to turn the socket in one direction with force and in the other direction without force, which allows you to tighten or loosen a bolt without removing and resetting the wrench after you have turned it. In many situations, a socket wrench is much safer, faster, and easier to use than any other wrench. In fact, sometimes it is the only wrench that will work.

The basic socket wrench set consists of a ratchet handle and several barrel-shaped sockets. The socket fits over and around a bolt or nut (**Figure 4-34**). Inside, it is shaped like a box-end wrench. Sockets are available in 6, 8, or 12 points. A 6-point socket has stronger walls and improved grip on a bolt compared to a normal 12-point socket. However, 6-point sockets have half the positions of a 12-point socket. Six-point sockets are mostly used on fasteners that are rusted or

Figure 4-33 Top: A handy tool containing many different Allen wrenches. Bottom: Tee-handle Allen wrenches designed for better gripping and easier torque application. Reproduced under license from Snap-on Incorporated. All of the marks are marks of their owners.

Figure 4-34 The size of the correct socket is the same size as the size of the bolt head or nut.

rounded. Eight-point sockets are available to use on square nuts or square-headed bolts. Some axle and transmission assemblies use square-headed plugs in the fluid reservoir.

Figure 4-35 An assortment of ratchets.

The top side of a socket has a square hole that accepts a square lug on the socket handle. This square hole is the drive hole. The size of the hole and handle lug ($\frac{1}{4}$ inch, $\frac{3}{8}$ inch, $\frac{1}{2}$ inch, and so on) indicates the drive size of the socket wrench. One handle fits all the sockets in a set. On better-quality handles, a spring-loaded ball in the square drive lug fits into a depression in the socket. This ball holds the socket to the handle. An assortment of socket (ratchet) handles is shown in **Figure 4-35**.

Not all socket handles are ratcheting. Some, called breaker bars, are simply long arms with a swivel drive used to provide extra torque onto a bolt to help loosen it. These are available in a variety of lengths and drive sizes. Sometimes nut drivers are used. These handles look like screwdrivers and have a drive shaft on the end of the shaft. Sockets and/or various attachments are inserted on the drive lug. These drivers are only used when bolt tightness is low.

Sockets are available in various sizes, lengths, and bore depths. Both standard SAE and metric socket wrench sets are necessary for automotive service. Normally, the larger the socket size, the longer the socket or the deeper the well. Deep-well sockets are made extra long to fit over bolt ends or studs. A spark plug socket is an example of a special purpose deep-well socket. Deep-well sockets are also good for reaching nuts or bolts in limited-access areas. Deep-well sockets should not be used when a regular-size socket will do the job. The longer socket develops more twist torque and tends to slip off the fastener.

Heavier-walled sockets are designed for use with an impact wrench and are called impact sockets. Most sockets are chrome-plated, except for impact sockets, which are not (**Figure 4-36**).

Figure 4-36 A chromed deep-well socket and an impact socket.

Figure 4-37 A typical set of socket drivers.

Special Sockets Screwdriver (including Torx® driver) and Allen wrench attachments are also available for use with a socket wrench. **Figure 4-37** shows a typical set of specialty socket drivers. These socket wrench attachments are very handy when a fastener cannot be loosened with a regular screwdriver. The leverage given by the ratchet handle is often just what it takes to break a stubborn screw loose.

Swivel sockets are also available. These sockets are fitted with a flexible joint that accommodates odd angles between the socket and the ratchet handle. These sockets are often used to work bolts that are difficult to reach.

Although crowfoot sockets are not really sockets, they are used with a ratchet or breaker bar. These sockets are actually the end of an open-end or line wrench made with a drive bore, which allows a ratchet to move the socket.

Extensions An extension is commonly used to separate the socket from the ratchet or handle. The extension moves the handle away from the bolt and makes the use of a ratchet more feasible. Extensions are

WARNING!

Never use a nonimpact socket with an impact wrench.

Figure 4-38 A flexible adapter is used when direct access to the bolt is not possible.

available in all common drive sizes and in a variety of lengths. The most common lengths are 1 inch, 3 inches, 6 inches, and 10 inches; however 2- and 3-foot extensions are also quite common. Flexible adapters are used with extensions to gain access to bolts that cannot be directly tightened or loosened (Figure 4-38).

Wobble extensions allow a socket to pivot slightly at the drive connection. This type of extension provides for a more positive connection to the socket than swivel joints but only allows approximately 16 degrees of flexibility.

Socket Adapters When sockets of a different drive size must be used with a particular ratchet or handle, an adapter can be inserted between the socket and the drive on the handle. An example of a common adapter is one that allows for the use of a $\frac{1}{4}$ -inch drive socket on a $\frac{3}{8}$ -inch drive ratchet.

Torque Wrenches

Torque wrenches (Figure 4-39) measure how tight a nut or bolt is. Many of a car's nuts and bolts should be tightened to a certain amount and have a torque specification that is expressed in foot-pounds (U.S.)

Figure 4-39 The common types of torque wrenches.

or Newton-meters (metric). A foot-pound is the work or pressure accomplished by a force of 1 pound through a distance of 1 foot. A Newton-meter is the work or pressure accomplished by a force of 1 kilogram through a distance of 1 meter.

A torque wrench is basically a ratchet or breaker bar with some means of displaying the amount of torque exerted on a bolt when pressure is applied to the handle. Torque wrenches are available with the various drive sizes. Sockets are inserted onto the drive and then placed over the bolt. As pressure is exerted on the bolt, the torque wrench indicates the amount of torque.

SHOP TALK

Following torque specifications is critical. However, there is a possibility that the torque spec is wrong as printed. (In other words, someone made a mistake.) If the torque spec seems way too tight or loose for the size of bolt, find the torque spec in a different source. If the two specs are the same, use it. If they are different, use the one that seems right.

The common types of torque wrenches are available with inch-pound and foot-pound increments.

- A beam torque wrench is not highly accurate. It relies on a beam metal that points to the torque reading.
- A “click”-type torque wrench clicks when the desired torque is reached. The handle is twisted to set the desired torque reading.
- A dial torque wrench has a dial that indicates the torque exerted on the wrench. The wrench may have a light or buzzer that turns on when the desired torque is reached.
- A digital readout type displays the torque and is commonly used to measure turning effort as well as for tightening bolts. Some designs of this type torque wrench have a light or buzzer that turns on when the desired torque is reached.

The correct torque provides the tightness and stress that the manufacturer has found to be the most desirable and reliable. For example, engine-bearing caps that are too tight distort the bearings, causing excessive wear and incorrect oil clearance. This often results in rapid wear of other engine parts due to decreased oil flow. Insufficient torque can result in out-of-round bores and subsequent failure of the parts.

PROCEDURE

When using a torque wrench, follow these steps to get an accurate reading:

1. Locate the torque specs and procedures in a service manual.
2. Mentally divide the torque specification by three.
3. Hold the wrench so that it is at a 90-degree angle from the fastener being tightened.
4. Tighten the bolt or nut to one-third of the specification.
5. Then tighten the bolt to two-thirds of the spec.
6. Now tighten the bolt to within 10 foot-pounds of the spec.
7. Tighten the bolt to the specified torque.
8. Recheck the torque.

Screwdrivers

A screwdriver drives a variety of threaded fasteners used in the automotive industry. Each fastener requires a specific kind of screwdriver, and a well-equipped technician has several sizes of each.

SHOP TALK

A screwdriver should not be used as a chisel, punch, or pry bar. Screwdrivers were not made to withstand blows or bending pressures. When misused in such a fashion, the tips will wear, become rounded, and tend to slip out of the fastener. At that point, a screwdriver becomes unusable. Remember a defective tool is a dangerous tool.

Screwdrivers are defined by their sizes, their tips (Figure 4-40), and the types of fasteners they should be used with. Your tool set should include both blade and Phillips drivers in a variety of lengths from 2-inch “stubbies” to 12-inch screwdrivers. You also should have an assortment of special screwdrivers, such as those with a Torx® head design.

- ✚ PHILLIPS TIP
- ✳ POZIDRIV® TIP
- ⚙ TORX® TIP
- ⚡ CLUTCH TIP
- SCRULOX® (SQUARE TIP)

Figure 4-40 The various screwdriver tips that are available. Reproduced under license from Snap-on Incorporated. All of the marks are marks of their owners.

Figure 4-41 The blade tip screwdriver is used with slotted head fasteners.

- **Standard Tip Screwdriver:** A slotted screw accepts a screwdriver with a standard or blade-type tip. The standard tip screwdriver is probably the most common type (Figure 4-41). It is useful for turning carriage bolts, machine screws, and sheet metal screws. The width and thickness of the blade determine the size of a standard screwdriver. Always use a blade that fills the slot in the fastener.
- **Phillips Screwdriver:** The tip of a **Phillips screwdriver** has four prongs that fit the four slots in a Phillips head screw (Figure 4-42). The four surfaces enclose the screwdriver tip so it is less likely that the screwdriver will slip out of the fastener. Phillips screwdrivers come in sizes #0 (the smallest), #1, #2, #3, and #4 (the largest).
- **Reed and Prince Screwdriver:** The tip of a Reed and Prince screwdriver is like a Phillips except that the prongs come to a point rather than to a blunt end.
- **Pozidriv® Screwdriver:** The **Pozidriv screwdriver** is like a Phillips but its tip is flatter and blunter. The squared tip grips the screw's head and slips less than a Phillips screwdriver.

Figure 4-42 The tip of a Phillips screwdriver has four prongs that provide a good grip in the fastener.

- **Torx® Screwdriver:** The **Torx screwdriver** is used to secure headlight assemblies, mirrors, and luggage racks. Not only does the six-prong tip provide greater turning power and less slippage, but the Torx fastener also provides a measure of tamper resistance. Torx drivers come in sizes T15 (the smallest), T20, T25, and T27 (the largest).
- **Clutch Driver:** Fasteners that require a clutch driver are normally used in non-load-bearing places. Clutch head fasteners offer a degree of tamper resistance and offer less slippage than a standard slot screw. The clutch head design has been called a butterfly or figure-eight. Automotive technicians do not often use these drivers.
- **Scrulox® Screwdriver:** The Scrulox screwdriver has a square tip. The tip fits into a square recess in the top of a fastener. This type of fastener is commonly used on truck bodies, campers, and boats.

Impact Screwdriver

An impact screwdriver is used to loosen stubborn screws. Impact screwdrivers have interchangeable heads and bits that allow the handles of the tools to be used with various screw head designs.

To use an impact screwdriver (**Figure 4-43**), select the correct bit and insert it into the driver's head. Then hold the bit against the screw slot while firmly

Figure 4-43 (A) An impact screwdriver set. (B) An impact screwdriver automatically tries to rotate the screw when it is struck with a hammer.

twisting the handle in the desired direction. Strike the handle with a hammer. The force of the hammer will exert a downward force on the screw and, at the same time, exert a twisting force on the screw.

Pliers

Pliers (**Figure 4-44**) are gripping tools used for working with wires, clips, and pins. At a minimum, an auto technician should own several types: standard pliers for common parts and wires, needle nose for small

Figure 4-44 Various types of pliers.

parts, and large, adjustable pliers for large items and heavy-duty work. A brief discussion on the different types of pliers follows:

- **Combination pliers** are the most common type of pliers and are frequently used in many kinds of automotive repair. The jaws have both flat and curved surfaces for holding flat or round objects. Also called slip-joint pliers, the combination pliers have many jaw-opening sizes. One jaw can be moved up or down on a pin attached to the other jaw to change the size of the opening.
- **Adjustable pliers**, commonly called *channel locks*, have a multiposition slip joint that allows for many jaw-opening sizes.
- **Needle nose pliers** have long, tapered jaws. They are great for holding small parts or for reaching into tight spots. Many needle nose pliers also have wire-cutting edges and a wire stripper. Curved needle nose pliers allow you to work on a small object around a corner.
- **Locking pliers**, or *vise grips*, are similar to the standard pliers, except they can be tightly locked around an object. They are extremely useful for holding parts together. They are also useful for getting a firm grip on a badly rounded fastener that is impossible to turn with a wrench or socket. Locking pliers come in several sizes and jaw configurations for use in many auto repair jobs.
- **Diagonal-cutting pliers**, or cutters, are used to cut electrical connections, cotter pins, and wires on a vehicle. Jaws on these pliers have extra-hard cutting edges that are squeezed around the item to be cut.
- **Snap- or lock ring pliers** are made with a linkage that allows the movable jaw to stay parallel throughout the range of opening (**Figure 4-45**). The jaw surface is usually notched or toothed to prevent slipping.

Figure 4-45 Snapping and retaining ring pliers.

- **Retaining ring pliers** are identified by their pointed tips that fit into holes in retaining rings. Retaining ring pliers come in fixed sizes but are also available in sets with interchangeable jaws.

Hammers

Hammers are identified by the material and weight of the head. There are two groups of hammer heads: steel and soft faced (**Figures 4-46** and **4-47**). Your tool set should include at least three hammers: two

Figure 4-46 Various steel-faced hammers. Reproduced under license from Snap-on Incorporated. All of the marks are marks of their owners.

Figure 4-47 Soft-faced hammers. *Reproduced under license from Snap-on Incorporated. All of the marks are marks of their owners.*

ball-peen hammers, one 8-ounce and one 12- to 16-ounce hammer, and a small sledgehammer. You should also have a plastic and lead or brass-faced mallet. The heads of steel-faced hammers are made from high-grade alloy steel. The steel is deep forged and heat treated to a suitable degree of hardness. Soft-faced hammers have a surface that yields when it strikes an object. Soft-faced hammers should be used on machined surfaces and when marring a finish is undesirable. For example, a brass hammer should be used to strike gears or shafts because it will not damage them.

Chisels and Punches

Chisels are used to cut metal by driving them with a hammer. Automotive technicians use a variety of

Figure 4-48 Punches are defined by their shape and the diameter of the point.

chisels for cutting sheet metal, shearing off rivet and bolt heads, splitting rusted nuts, and chipping metal. A variety of chisels are available, each with a specific purpose, including flat, cape, round-nose cape, and diamond point chisels.

Punches (Figure 4-48) are used for driving out pins, rivets, or shafts; aligning holes in parts during assembly; and marking the starting point for drilling a hole. Punches are designated by their point diameter and punch shape. Drift punches are used to remove drift and roll pins. Some drifts are made of brass; these should be used whenever you are concerned about possible damage to the pin or to the surface surrounding the pin. Tapered punches are used to line up bolt holes. Starter or center punches are used to make an indent before drilling to prevent the drill bit from wandering.

Removers

Rust, corrosion, and prolonged heat can cause automotive fasteners, such as cap screws and studs, to become stuck. A box wrench or socket is used to loosen cap screws. A special gripping tool is designed to remove studs. However, if the fastener breaks off, special extracting tools and procedures must be employed.

One type of stud remover is shown in Figure 4-49. These tools are also used to install studs. Stud removers have hardened, knurled, or grooved eccentric rollers or jaws that grip the stud tightly when operated. Stud removers/installers are turned by a socket wrench drive handle, a socket, or wrench.

Extractors are used on screws and bolts that are broken off below the surface. Twist drills, fluted extractors, and hex nuts are included in a screw extractor set (Figure 4-50). This type of extractor lessens the tendency to expand the screw or stud that has

Figure 4-49 Stud installation/removal tool.

Figure 4-50 Screw extractors.

been drilled out by providing gripping power along the full length of the stud.

Screw extractors are often called easy outs. To use an extractor, the bolt must be drilled and the extractor forced into that bore. The teeth of the extractor grip the inside of the drilled bore and allow the bolt to be turned out (**Figure 4-51**). Easy outs typically have the size of the required drill bit stamped on one side.

At times a broken bolt can be loosened and removed from its bore by driving it in a counterclockwise direction with a chisel and hammer. A bolt broken off above the surface may be able to be removed with locking pliers.

Hacksaws

A hacksaw is used to cut metal (**Figure 4-52**). The blade only cuts on the forward stroke. The teeth of the blade should always face away from the saw's handle.

Figure 4-51 Using a screw extractor to remove a broken bolt.

Figure 4-52 (A) The teeth on the blade in a hacksaw should face forward. (B) A coarse blade should not be used with sheet metal. (C) A fine blade will work well with sheet metal.

The number of teeth on the blade determines the type of metal the saw can be used on. A fine-toothed blade is best for thin sheet metal, whereas a coarse blade is used on thicker metals.

When using a hacksaw, never bear down on the blade while pulling it toward you; this will dull the blade. Use the entire blade while cutting.

Files

Files are commonly used to shape or smooth metal edges. Files typically have square, triangular, rectangular (flat), round, or half-round shapes (**Figure 4-53**). They also vary in size and coarseness. The most commonly used files are the half-round and flat with either single-cut or double-cut designs. A single-cut file has its cutting grooves lined up diagonally across the face of the file. The cutting grooves of a double-cut file run diagonally in both directions across the

Figure 4-53 (A) Files come in a variety of shapes. Courtesy of Ford Motor Company (B) A file card.

face. Double-cut files are considered first cut or roughening files because they can remove large amounts of metal. Single-cut files are considered finishing files because they remove small amounts of metal.

To avoid personal injury, files should always be used with a plastic or wooden handle. Like hacksaws, files only cut on the forward stroke. Coarse files are used for soft metals, and smoother, or finer, files are used to work steel and other hard metals.

Keep files clean, dry, and free of oil and grease. To clean filings from the teeth of a file, use a special tool called a file card.

Gear and Bearing Pullers

Many precision gears and bearings have a slight interference fit (**press fit**) when installed on a shaft or housing. For example, the inside diameter of a bore is 0.001 inch smaller than the outside diameter of a shaft. When the shaft is fitted into the bore it must be pressed in to overcome the 0.001-inch interference fit. This press fit prevents the parts from moving on each other. The removal of gears and bearings must be done carefully. Prying or hammering can break or bind the parts. A puller with the proper jaws and adapters should be used when applying force to remove gears and bearings. Using proper tools, the force can be applied with a slight and steady motion.

Pullers are available in many different designs and therefore are designed for specific purposes. Most pullers come with various jaw lengths and shapes to allow them to work in a number of different situations.

Some pullers are fitted to the end of a slide hammer (**Figure 4-54**) and are used to remove slightly press-fit items. After the mounting plate of the puller is secure in or on the object to be removed, the weight on the tool's hammer is slid back with force against

Figure 4-54 Using a slide hammer-type puller to remove a drive axle.

the handle of the tool, generating a pulling force and jerking the object out of its bore.

To pull something out of a bore, the puller must be designed to expand its jaws outward. The jaws also must be small enough to reach into the bore without damaging the bore while still firmly gripping the object that is being removed. This type puller is commonly used to remove seals, bushings, and bearing cups.

Jaw-type pullers are used to pull an object off a shaft. These pullers are available with two or three jaws (**Figure 4-55**). Jaw-type pullers are commonly used to remove bearings, pulleys, and gears.

Some pullers are actually pushers. A push-puller is used to push a shaft out of its bore in a housing. It is often difficult to grip the end of the shaft with a puller, so a push-puller is used to move the shaft out of the bore.

Bearing, Bushing, and Seal Drivers

Another commonly used group of special tools includes the various designs of bearing, bushing, and

Figure 4-55 The jaws on this puller are reversible to allow for inside and outside pulls.

seal drivers. Auto manufacturers supply their dealerships with drivers for specific components. However, universal sets of drivers are also available. These sets include a variety of driver plates, each of a different diameter. The plates are often reversible. The flat side of the plate is used to install seals and the tapered side is used to install tapered bearing races. A driver handle is threaded into the appropriate plate. The bearing or seal is driven into place by tapping on the driver hammer.

Always make sure you use the correct tool for the job; bushings and seals are easily damaged if the wrong tool or procedure is used. Car manufacturers and specialty tool companies work closely together to design and manufacture special tools required to repair cars.

Trouble Light

Adequate light is necessary when working under and around automobiles. A **trouble light** can be battery powered (like a flashlight) or need to be plugged into a wall socket. Some shops have trouble lights that pull down from a reel suspended from the ceiling. Trouble lights should have LED or fluorescent bulbs. Incandescent bulbs should not be used because they can pop and burn. Take extra care when using a trouble light. Make sure its cord does not get caught in a rotating object. The bulb or tube should be surrounded by a cage or enclosed in clear plastic to prevent accidental breaking and burning.

Creeper

Rather than crawl on your back to work under a vehicle, use a creeper (**Figure 4-56**). A creeper is a platform with small wheels. It allows you to slide under a vehicle and easily maneuver while working. To protect yourself and others around you, never have the creeper lying on the floor when you are not using it.

Figure 4-56 A creeper allows you to work comfortably and safely under a vehicle.

Accidentally stepping on it can result in a serious fall. Always keep it standing on its end when it is not being used.

SHOP EQUIPMENT

Some tools and equipment are supplied by the service facility and few technicians have these as part of their tool assortment. These tools are commonly used but there is no need for each technician to own them. Many shops have one or two of each.

Bench Vises

Often repair work is completed with a part or assembly removed from the vehicle. The repairs are typically safely and quickly made by securing the assembly. Small parts are usually secured with a bench vise. The vise is bolted to a workbench to give it security. The object to be held is placed into the tool's jaws and the jaws are tightened around the object. If the object could be damaged or marred by the jaws, brass jaw caps are installed over the jaws before the object is placed between them.

Bench Grinder

This electric power tool is generally bolted to a workbench. The grinder should have safety shields and guards. Always wear face protection when using a grinder. A bench grinder is classified by wheel size. Six- to ten-inch wheels are the most common in auto repair shops. Three types of wheels are available with this bench tool:

1. Grinding wheel, for a wide variety of grinding jobs from sharpening cutting tools to deburring
2. Wire wheel brush, for general cleaning and buffing, removing rust, scale, and paint, deburring, and so forth
3. Buffing wheel, for general purpose buffing, polishing, and light cutting

Presses

Many automotive jobs require the use of powerful force to assemble or disassemble parts that are press fit together. Removing and installing piston pins, servicing rear axle bearings, pressing brake drum and rotor studs, and performing transmission assembly work are just a few examples. Presses can be hydraulic, electric, air, or hand driven. Capacities range up to 150 tons of pressing force, depending on the size and design of the press. Smaller arbor and C-frame presses can be bench or pedestal mounted, while high-capacity units are freestanding or floor mounted (**Figure 4-57**).

Figure 4-57 A floor-mounted hydraulic press.

WARNING!

Always wear safety glasses when using a press.

Grease Guns

Some shops are equipped with air-powered grease guns, while in others, technicians use a manually operated grease gun. Both types can force grease into a grease fitting. Hand-operated grease guns are often preferred because the pressure of the grease can be controlled by the technician. However, many shops use low air pressure to activate a pneumatic grease gun. The suspension and steering system may have several grease or zerk fittings.

Oxyacetylene Torches

Oxyacetylene torches (**Figure 4-58**) have many purposes. In the automotive service industry they are used to heat metal when two parts are difficult to separate, to cut metal (such as when replacing exhaust system parts), and to weld or connect two metal parts together.

Oxyacetylene welding and cutting equipment uses the combustion of acetylene in oxygen to produce a flame temperature of about 5,600°F (3,100°C). Acetylene is used as the fuel and oxygen is used to aid in the combustion of the fuel.

Figure 4-58 Oxyacetylene welding equipment shown with a cutting torch.

The equipment includes cylinders of oxygen and acetylene, two pressure regulators, two flexible hoses (one for each cylinder), and a torch. The torches are selected for the job being done—welding torch for welding, brazing, soldering, and heating and cutting torch for cutting metal.

There are three sets of valves for each gas: the tank valve, the regulator valve, and the torch valve. The oxygen hose is colored green, and the acetylene hose is red. The acetylene connections have left-hand threads and the oxygen connectors have right-hand threads.

Welding and Heating Torch The hoses connect the cylinders to the torch. On the torch there are separate valves for each gas. The torch is comprised of the valves, a handle, a mixing chamber (where the fuel gas and oxygen mix), and a tip (where the flame forms). Many different tips can be used with a welding torch. Always select the correct size for the job.

Cutting Torch A cutting torch is used to cut metal. It is similar to a welding torch. However, the cutting torch has a third tube from the valves to the mixing chamber. It carries high-pressure oxygen, which is controlled by a large lever on the torch. During cutting, the metal is heated until it glows orange, and then a lever on the torch is pressed to pass a stream of oxygen through the heated metal to burn it away where the cut is desired.

Precautions Never use oxyacetylene equipment unless you have been properly trained to do so. Also, adhere to all safety precautions, including:

- Always pay attention to what you are doing: While using a torch, severe and fatal burns and violent explosions can result from inattention and carelessness.
- Before using an oxyacetylene torch, make sure that all flammable materials such as grease, oil, paint, sawdust, and so on are cleared from the area.
- Keep oxygen away from all combustibles.
- Wear approved shaded goggles with enclosed sides, or a shield with a shaded lens to protect your eyes from glare and sparks.
- Wear leather gloves to protect your hands from burns.
- Wear clothes and shoes/boots appropriate for welding. They should be free of grease and oil.
- Make sure that the gas cylinders are securely fastened upright to a wall or a post or a portable cart.

- Never move an oxygen tank around without its valve cap screwed in place.
- Never lay an acetylene tank on its side while being used.
- Never oil an oxygen regulator.

POWER TOOLS

Power tools make a technician's job easier. They operate faster and with more torque than hand tools. However, power tools require greater safety measures. Power tools do not stop unless they are turned off. Power is furnished by air (pneumatic), electricity, or hydraulic fluid. *Power tools should only be used for loosening nuts and/or bolts.*

SHOP TALK

Safety is critical when using power tools. Carelessness or mishandling of power tools can cause serious injury. Do not use a power tool without obtaining permission from your instructor. Be sure you know how to operate the tool properly before using it. Prior to using a power tool, read the instructions carefully.

Impact Wrench

An **impact wrench** (Figure 4-59) is a portable hand-held reversible wrench. A heavy-duty model can deliver up to 450 foot-pounds (607.5 N·m) of torque. When triggered, the output shaft, onto which the impact socket is fastened, spins freely at 2,000 to 14,000 rpm, depending on the wrench's make and model. When the impact wrench meets resistance, a small spring-loaded hammer situated near the end of the tool strikes an anvil attached to the drive shaft onto which the socket is mounted. Each impact moves the socket around a little until torque equilibrium is reached, the fastener breaks, or the trigger is

Figure 4-59 A typical air impact wrench.

released. Torque equilibrium occurs when the torque of the bolt equals the output torque of the wrench. Impact wrenches can be powered either by air or by electricity.

SHOP TALK

When using an air impact wrench, it is important that only impact sockets and adapters be used. Other types of sockets and adapters, if used, might shatter and fly off, endangering the safety of the operator and others in the immediate area.

An impact wrench uses compressed air or electricity to hammer or impact a nut or bolt loose or tight. Light-duty impact wrenches are available in three drive sizes— $\frac{1}{4}$, $\frac{3}{8}$, and $\frac{1}{2}$ inch—and two heavy-duty sizes— $\frac{3}{4}$ and 1 inch.

WARNING!

Impact wrenches should not be used to tighten critical parts or parts that may be damaged by the hammering force of the wrench.

Air Ratchet

An air ratchet, like the hand ratchet, has a special ability to work in hard-to-reach places. Its angle drive reaches in and loosens or tightens where other hand or power wrenches just cannot work (Figure 4-60). The air ratchet looks like an ordinary ratchet but has a fat handgrip that contains the air vane motor and drive mechanism. Air ratchets usually have a $\frac{3}{8}$ -inch drive. Air ratchets are not torque sensitive; therefore, a torque wrench should be used on all fasteners after snugging them up with an air ratchet.

Figure 4-60 An air ratchet.

Air Drill

Air drills are usually available in $\frac{1}{4}$ -, $\frac{3}{8}$ -, and $\frac{1}{2}$ -inch sizes. They operate in much the same manner as an electric drill, but are smaller and lighter. This compactness makes them a great deal easier to use for drilling operations in auto work.

Blowgun

Blowguns are used for blowing off parts during cleaning. Never point a blowgun at yourself or anyone else. A blowgun (Figure 4-61) snaps into one end of an air hose and directs airflow when a button is pressed. Always use an OSHA-approved air blowgun. Before using a blowgun, be sure it has not been modified to eliminate air-bleed holes on the side.

JACKS AND LIFTS

Jacks are used to raise a vehicle off the ground and are available in two basic designs and in a variety of sizes. The most common jack is a hydraulic floor jack, which is classified by the weights it can lift: $1\frac{1}{2}$, 2, and $2\frac{1}{2}$ tons, and so on. These jacks are controlled by moving the handle up and down. The other design of portable floor jack uses compressed air. Pneumatic jacks are operated by controlling air pressure at the jack.

CAUTION!

Before lifting a vehicle with air suspension, turn off the system. The switch is usually in the trunk.

The hydraulic floor lift is the safest lifting tool and is able to raise the vehicle high enough to allow you to walk and work under it. Various safety features prevent a hydraulic lift from dropping if a seal does leak or if air pressure is lost. Before lifting a vehicle, make sure the lift is correctly positioned.

Floor Jack

A floor jack is a portable unit mounted on wheels. The lifting pad on the jack is placed under the chassis of the vehicle, and the jack handle is operated with a pumping action. This forces fluid into a hydraulic cylinder in the jack, and the cylinder extends to force the jack lift pad upward and to lift the vehicle. Always be sure that the lift pad is positioned securely under one of the car manufacturer's recommended lifting points. To release the hydraulic pressure and lower the vehicle, the handle or release lever must be turned slowly.

Figure 4-61 Two types of air nozzles (blowguns).

The maximum lifting capacity of the floor jack is usually written on the jack decal. Never lift a vehicle that exceeds the jack lifting capacity. This action may cause the jack to break or collapse, resulting in vehicle damage or personal injury.

When a vehicle is raised by a floor jack, it should be supported by safety stands (**Figure 4-62**). Never work under a car with only a jack supporting it; always

use safety stands. Hydraulic seals in the jack can let go and allow the vehicle to drop.

Lift

A lift is used to raise a vehicle so the technician can work under the vehicle. The lift arms must be placed under the car manufacturer's recommended lifting points prior to raising a vehicle. There are three basic types of lifts: frame contact (**Figure 4-63**), wheel contact, and axle engaging. These categories define where the frame contact points align with the vehicle.

Twin posts are used on some lifts (**Figure 4-64**), whereas other lifts have a single post (**Figure 4-65**). Some lifts have an electric motor, which drives a hydraulic pump to create fluid pressure and force the lift upward. Other lifts use air pressure from the shop air supply to force the lift upward. If shop air pressure is used for this purpose, the air pressure is applied to fluid in the lift cylinder. A control lever or switch is placed near the lift. The control lever supplies shop air pressure to the lift cylinder, and the switch turns on the lift pump motor. Always be sure that the safety lock is engaged after the lift is raised (**Figure 4-66**). When the safety lock is released, a release lever is operated slowly to lower the vehicle.

Figure 4-62 Whenever you have raised a vehicle with a floor jack, the vehicle should be supported with jack stands.

Figure 4-63 An aboveground or surface mount frame-contact lift. *Courtesy of Automotive Lift Institute*

Figure 4-65 The typical setup for a single post lift. *Courtesy of Automotive Lift Institute*

Figure 4-64 The typical setup for a twin post lift. *Courtesy of Automotive Lift Institute*

Figure 4-66 Make sure the locking device or safety is fully engaged after the vehicle has been raised to the desired height. *Courtesy of Automotive Lift Institute*

Figure 4-67 Foot pads on the arms of a lift.
Courtesy of Automotive Lift Institute

The arms of a lift are fitted with **foot pads** (Figure 4-67) or adapters that can be lifted up to contact the vehicle's lift points to add clearance between the arms and the vehicle. This clearance allows for secure lifting without damaging any part of the body or underbody of the vehicle.

Portable Crane

To remove and install an engine, a portable crane, frequently called a cherry picker, is used. To lift an engine, attach a pulling sling or chain to the engine. Some engines have eye plates for use in lifting. If they are not available, the sling must be bolted to the engine. The sling attaching bolts must be large enough to support the engine and must thread into the block a minimum of $1\frac{1}{2}$ times the bolt diameter. Connect the crane to the chain. Raise the engine slightly and make sure the sling attachments are secure. Carefully lift the engine out of its compartment.

Lower the engine close to the floor so the transmission and torque converter or clutch can be removed from the engine, if necessary.

Engine Stands/Benches

After the engine has been removed, use the crane to raise the engine. Position the engine next to an engine stand. Most stands use a plate with several holes or adjustable arms. The engine must be supported by at least four bolts that fit solidly into the engine. The engine should be positioned so that its center is in the middle of the engine's stand adapter plate. The adapter plate can swivel in the stand. By centering the engine, the engine can be easily turned to the desired working positions.

Some shops have engine mounts bolted to the top of workbenches. The engine is suspended off the side of the workbench. These have the advantage of a good working space next to the engine, but they are not

mobile and all engine work must be done at that location.

After the engine is secured to its mount, the crane and lifting chains can be removed and disassembly of the engine can begin.

SERVICE INFORMATION

Perhaps the most important tools you will use are service manuals (Figure 4-68). There is no way a technician can remember all of the procedures and specifications needed to repair an automobile correctly. Thus, a good technician relies on service manuals and other sources for this information. Good information plus knowledge allows a technician to fix a problem with the least amount of frustration and at the lowest cost to the customer.

Auto Manufacturers' Service Manuals

The primary source of repair and specification information for any car, van, or truck is the manufacturer. The manufacturer publishes service manuals each year, for every vehicle built. These manuals are written for professional technicians.

Because of the enormous amount of information, some manufacturers publish more than one manual per year per car model. They may be separated into sections such as chassis, suspension, steering, emission control, fuel systems, brakes, basic maintenance, engine, transmission, body, and so on (Figure 4-69).

When complete information with step-by-step testing, repair, and assembly procedures is desired, nothing can match auto manufacturers' repair manuals. They cover all repairs, adjustments, specifications, detailed diagnostic procedures, and special

Figure 4-68 One of your most important tools is a service manual.

INDEX	
Alphabetical Index	

Figure 4-69 The main index of a factory service manual showing that the manual is divided by major vehicle systems.

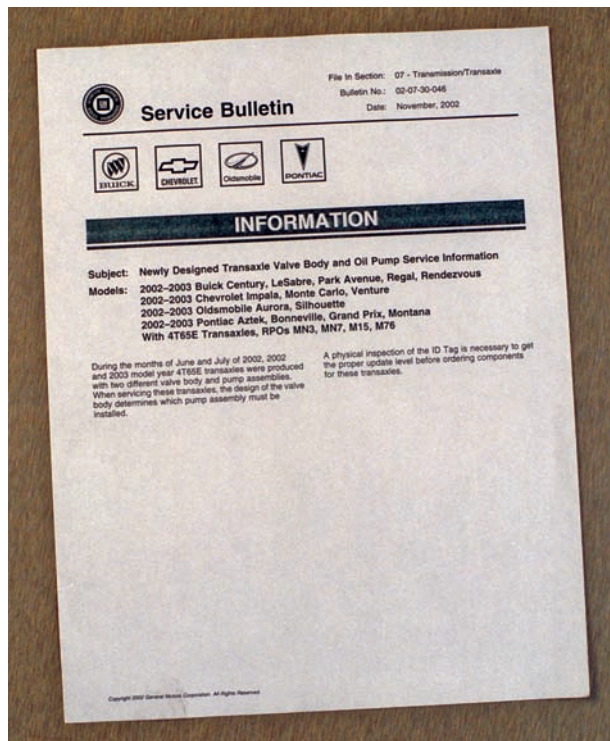

Figure 4-70 A technical service bulletin.

tools required. They can be purchased directly from the automobile manufacturer.

To help you learn how to effectively use service manuals, you will find service manual references and tips throughout this text.

Since many technical changes occur on specific vehicles each year, manufacturers' service manuals need to be constantly updated. Updates are published as service bulletins (often referred to as technical service bulletins or TSBs) that show the changes in specifications and repair procedures during the model year (**Figure 4-70**). These changes do not appear in the service manual until the next year. The car manufacturer provides these bulletins to dealers and repair facilities on a regular basis.

Automotive manufacturers also publish a series of technician reference books. The publications provide general instructions about the service and repair of the manufacturers' vehicles and also indicate their recommended techniques.

General and Specialty Repair Manuals

Service manuals are also published by independent companies rather than the manufacturers. However, they pay for and get most of their information from the car makers. The manuals contain component information, diagnostic steps, repair procedures, and specifications for several makes of automobiles in one book. Information is usually condensed and is more general than the manufacturers' manuals. The

condensed format allows for more coverage in less space and, therefore, is not always specific. They may also contain several years of models as well as several makes in one book.

Finding Information in Service Manuals

Although the manuals from different publishers vary in presentation and arrangement of topics, all service manuals are easy to use after you become familiar with their organization. Most shop manuals are divided into a number of sections, each covering different aspects of the vehicle. The beginning sections commonly provide vehicle identification and basic maintenance information. The remaining sections deal with each different vehicle system in detail, including diagnostic, service, and overhaul procedures. Each section has an index indicating more specific areas of information.

To obtain the correct system specifications and other information, you must first identify the exact system you are working on. The best source for vehicle identification is the VIN. The code can be interpreted through information given in the service manual. The manual may also help you identify the system through identification of key components or other identification numbers and/or markings.

To use a service manual:

1. Select the appropriate manual for the vehicle being serviced.
2. Use the table of contents to locate the section that applies to the work being done.
3. Use the index at the front of that section to locate the required information.
4. Carefully read the information and study the applicable illustrations and diagrams.
5. Follow all of the required steps and procedures given for that service operation.
6. Adhere to all of the given specifications and perform all measurement and adjustment procedures with accuracy and precision.

Aftermarket Suppliers' Guides and Catalogs

Many of the larger parts manufacturers have excellent guides on the various parts they manufacture or supply. They also provide updated service bulletins on their products. Other sources for up-to-date technical information are trade magazines and trade associations.

Lubrication Guides

These specially designed service manuals contain information on lubrication, maintenance, capacities,

and underhood service. The lubrication guide includes lube and maintenance instructions, lubrication diagrams and specifications, vehicle lift points, and preventive maintenance mileage/time intervals. The capacities listed include cooling system, air conditioning, cooling system air bleed locations, wheel and tire specifications, and wheel lug torque specifications. The underhood information includes specifications for tune-up; mechanical, electrical, and fuel systems; diagrams; and belt tension.

Owner's Manuals

An owner's manual comes with the vehicle when it is new. It contains operating instructions for the vehicle and its accessories. It also contains valuable information about checking and adding fluids, safety precautions, a complete list of capacities, and the specifications for the various fluids and lubricants for the vehicle.

Flat-Rate Manuals

Flat-rate manuals contain standards for the length of time a specific repair is supposed to require. Normally, they also contain a parts list with approximate or exact prices of parts. They are excellent for making cost estimates and are published by the manufacturers and independents.

Computer-Based Information

Most technicians no longer rely on printed copies of service manuals. They access the same information, as well as service bulletins, electronically on **compact disk-read-only memory (CD-ROMs)** (Figure 4-71), digital video disks (DVDs), and the Internet. Computer-based information eliminates the need for a huge library of printed manuals. Using electronics to find information is also easier and quicker. The disks are normally updated monthly and

Figure 4-71 The use of CD-ROMs and a computer makes accessing information quick and easy. Courtesy of Robert Bosch GmbH, www.bosch-presse.de

Figure 4-72 The computer screen can display everything that would be in a printed service manual, but computer systems are quicker and using them makes finding information easier.

not only contain the most recent service bulletins but also engineering and field service fixes. DVDs hold more information than CDs; therefore, there are fewer disks with systems that use DVDs.

A technician enters vehicle information and then selects the appropriate part or system (Figure 4-72). The appropriate information then appears on the computer's screen. Online data can be updated instantly and requires no space for physical storage. These systems are easy to use and the information is quickly accessed and displayed. Once the information is retrieved, a tech can read it off the screen or print it out and take it to the service bay.

Hotline Services

Hotline services provide answers to service concerns by telephone. Manufacturers provide help by telephone for technicians in their dealerships. There are subscription services for independents to be able to get repair information by phone. Some manufacturers also have a phone modem system that can transmit computer information from the car to another location. The vehicle's diagnostic link is connected to the modem. The technician in the service bay runs a test sequence on the vehicle. The system downloads the latest updated repair information on that particular model of car. If that does not repair the problem, a technical specialist at the manufacturer's location will review the data and propose a repair.

iATN

The International Automotive Technician's Network (iATN) is comprised of a group of thousands of professional automotive technicians from around the world. The technicians in this group exchange technical knowledge and information with other members. The Web address for this group is <http://www.iatn.net>.

KEY TERMS

Ball gauge	Micrometer
Blowgun	Phillips screwdriver
Bolt diameter	Pliers
Bolt head	Pozidriv screwdriver
Bolt shank	Press fit
Chisel	Punch
Compact disk-read-only memory (CD-ROM)	Snap gauge
Dial caliper	Spark plug thread tap
Dial indicator	Straightedge
Die	Tap
Extractor	Telescoping gauge
Feeler gauge	Thread pitch
Fillet	Thread pitch gauge
Foot pads	Torque wrench
Grade marks	Torx screwdriver
Impact wrench	Trouble light
Machinist's rule	Vernier caliper
	Wrench

SUMMARY

- Repairing the modern automobile requires the use of many different hand and power tools. Units of measurement play a major role in tool selection. Therefore, it is important to be knowledgeable about the Imperial and the metric systems of measurement.
- Measuring tools must be able to measure objects to a high degree of precision. They should be handled with care at all times and cleaned before and after every use.
- A micrometer can be used to measure the outside diameter of shafts and the inside diameter of holes. It is calibrated in either inch or metric graduations.
- Telescoping gauges are designed to measure bore diameters and other clearances. They usually are used with an outside micrometer. Small hole gauges are used in the same manner as the

telescoping gauge, usually to determine valve guide diameter.

- The screw pitch gauge provides a fast and accurate method of measuring the threads per inch (pitch) of fasteners. This is done by matching the teeth of the gauge with the fastener threads and reading the pitch directly from the leaf of the gauge.
- It is crucial to use the proper amount of torque when tightening nuts or cap screws on any part of a vehicle, particularly the engine. A torque-indicating wrench makes it possible to duplicate the conditions of tightness and stress recommended by the manufacturer.
- Metric and SAE size wrenches are not interchangeable. An auto technician should have a variety of both types.
- A screwdriver, no matter what type, should never be used as a chisel, punch, or pry bar.
- The hand tap is used for hand cutting internal threads and for cleaning and restoring previously cut threads. Hand-threading dies cut external threads and fit into holders called die stocks.
- Carelessness or mishandling of power tools can cause serious injury. Safety measures are needed when working with such tools as impact and air ratchet wrenches, blowguns, bench grinders, lifts, hoists, and hydraulic presses.
- The primary source of repair and specification information for any vehicle is the manufacturer's service manual. Updates are published as service bulletins and include changes made during the model year, which will not appear in the manual until the following year.
- Flat-rate manuals are ideal for making cost estimates. Published by manufacturers and independent companies, they contain figures showing how long specific repairs should take to complete, as well as a list of the necessary parts and their prices.

REVIEW QUESTIONS

1. How often should the calibration of a micrometer be checked?
2. List some common uses of the dial indicator.
3. Wrenches are marked with their size. What does the size represent?
4. *True or False?* The same information available in service manuals and bulletins is also available

- electronically: on compact disks (CD-ROMs), digital video disks (DVDs), and the Internet.
5. How do manufacturers inform technicians about changes in vehicle specifications and repair procedures during the model year?
 6. Which of the following wrenches is the best choice for turning a bolt?
 - a. open-end
 - b. box-end
 - c. combination
 - d. none of the above
 7. Technician A says that a vernier caliper can be used to measure the outside diameter of something. Technician B says that a vernier caliper can be used to measure the inside diameter of a bore. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
 8. Technician A says that a tap cuts external threads. Technician B says that a die cuts internal threads. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
 9. Which of the following screwdrivers is like a Phillips but has a flatter and blunter tip?
 - a. standard
 - b. Torx®
 - c. Pozidriv®
 - d. clutch head
 10. Which of the following types of pliers is best for grasping small parts?
 - a. adjustable
 - b. needle nose
 - c. retaining ring
 - d. snapping
 11. Technician A uses a punch to align holes in parts during assembly. Technician B uses a punch to drive out rivets. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
 12. An extractor is used for removing broken _____.
 - a. seals
 - b. bushings
 - c. pistons
 - d. bolts
 13. Which of the following statements about items that are press fit is *not* true?
 - a. Many precision gears and bearings have a slight interference fit when installed on a shaft or housing.
 - b. The press fit allows slight motion between the parts and therefore prevents wear.
 - c. The removal of gears and bearings that are press fit must be done carefully to avoid breaking or binding the parts.
 - d. A puller with the proper jaws and adapters should be used when applying force to remove press-fit gears and bearings.
 14. Technician A uses a blowgun to blow off parts during cleaning. Technician B uses a blowgun to clean off his uniform after working. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
 15. Technician A says that flare nut or line wrenches should be used to loosen or tighten brake line or tubing fittings. Technician B says that open-end wrenches will surround the fitting's nut and provide a positive grip on the fitting. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
 16. Technician A uses a dial caliper to take inside and outside measurements. Technician B uses a dial caliper to take depth measurements. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
 17. For a measurement that must be made within one ten-thousandth of an inch, Technician A uses a machinist's rule. For the same accuracy, Technician B uses a standard micrometer. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
 18. Technician A says that portable floor jacks are operated by hydraulics. Technician B says that portable floor jacks may be operated by compressed air. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
 19. When using an air impact wrench, Technician A uses impact sockets and adapters. Technician B uses chrome-plated sockets. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
 20. While discussing thread sealants and lubricants: Technician A says that antiseize compound is used where a bolt might become difficult to remove after a period of time. Technician B says that thread sealants are used on bolts that are

tightened into an oil cavity or coolant passage. Who is correct?

- a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
21. The metric equivalent to 10 miles is _____.
a. 0.06895 bar c. 1.6093 kilometers
b. 10.6895 bars d. 16.093 kilometers
22. *True or False?* A metric bolt with the marking of 8.9 has more yield strength than a bolt marked 10.5.
23. List the steps that should be followed to precisely tighten a bolt to specifications.
24. Which of the following thread designs typically has tapered threads to provide for sealing at a joint?
a. UNC c. UNF
b. NPT d. UNEF
25. Which of the following is *not* measured with a feeler gauge set?
a. piston ring side clearance
b. flywheel runout
c. crankshaft end play
d. spark plug gap

DIAGNOSTIC EQUIPMENT AND SPECIAL TOOLS

OBJECTIVES

- Describe the various diagnostic tools used to check an engine and its related systems.
- Describe the common tools used to service an engine and its related systems.
- Describe the various diagnostic tools used to check electrical and electronic systems.
- Describe the common tools used to service electrical and electronic systems.
- Describe the various diagnostic tools used to check engine performance systems.
- Describe the common tools used to service engine performance systems.
- Describe the various diagnostic tools used to check hybrid vehicles.
- Describe the various diagnostic tools used to check a vehicle's drivetrain.
- Describe the common tools used to service a vehicle's drivetrain.
- Describe the various diagnostic tools used to check a vehicle's running gear for wear and damage.
- Describe the common tools used to service a vehicle's running gear.
- Describe the various diagnostic tools used to check a vehicle's heating and air-conditioning system.
- Describe the common tools used to service a vehicle's heating and air-conditioning system.

Diagnosing and servicing the various systems of an automobile require many different tools. Tools that are used to check the performance of a system or component are commonly referred to as diagnostic tools. Tools designed for a particular purpose or system are referred to as special tools. This chapter looks at the common diagnostic and special tools required to service the different systems of a vehicle.

ENGINE REPAIR TOOLS

Engine repair (**Figure 5-1**) and diagnostic tools are discussed in the following paragraphs. This discussion does not cover all of the tools you may need: Only the most commonly used are discussed. Details of when and how to use these tools are presented in Section 2 of this book.

Compression Testers

The operation of an engine depends on the compression of the air-fuel mixture within its cylinders. If the combustion chamber leaks, some of the mixture will escape while it is being compressed, resulting in a loss of power and a waste of fuel.

A **compression gauge** is used to check cylinder compression. The dial face on the gauge indicates

pressure in both pounds per square inch (psi) and metric kilopascals (kPa). The range is usually 0 to 300 psi and 0 to 2,100 kPa. There are two basic types of compression gauges: the push-in gauge (**Figure 5-2**) and the screw-in gauge.

The push-in type has a short stem that is either straight or bent at a 45-degree angle. The stem ends in a tapered rubber tip that fits any size spark plug hole. After the spark plugs have been removed, the rubber tip is placed in the spark plug hole and held there while the engine is cranked through several compression cycles. Although simple to use, the push-in gauge may give inaccurate readings if it is not held tightly in the hole.

The screw-in gauge has a long, flexible hose that ends in a threaded adapter (**Figure 5-3**). This type of compression tester is often used because its flexible hose can reach into areas that are difficult to reach with a push-in-type tester. The threaded adapters are changeable and come in several thread sizes to fit 10 mm, 12 mm, 14 mm, and 18 mm diameter holes. The adapters screw into the spark plug holes in place of the spark plugs.

Most compression gauges have a vent valve that holds the highest pressure reading on its meter.

Figure 5-1 Proper engine rebuilding requires many different tools.

Figure 5-2 A push-in compression gauge.

Opening the valve releases the pressure when the test is complete.

Cylinder Leakage Tester

If a compression test shows that any of the cylinders are leaking, a cylinder leakage test can be performed to measure the percentage of compression lost and help locate the source of leakage.

Figure 5-3 A screw-in compression gauge set.

Figure 5-4 A cylinder leakage tester.

A **cylinder leakage tester** (Figure 5-4) applies compressed air to a cylinder, with the piston at the top of its bore, through the spark plug hole. A threaded adapter on the end of the air pressure hose screws into the spark plug hole. A pressure regulator in the tester controls the pressure applied to the cylinder. A gauge registers the percentage of air pressure lost

from the cylinder when the compressed air is applied. The scale on the dial face reads 0% to 100%.

A zero reading means there is no leakage in the cylinder. A reading of 100% indicates that the cylinder will not hold any pressure. The location of the compression leak can be found by listening and feeling around various parts of the engine.

Oil Pressure Gauge

Checking the engine's oil pressure gives information about the condition of the oil pump, the pressure regulator, and the entire lubrication system. Lower-than-normal oil pressures can be caused by excessive engine bearing clearances. Oil pressure is checked at the sending unit passage with an externally mounted mechanical oil pressure gauge. Various fittings are usually supplied with the oil pressure gauge to fit different openings in the lubrication system.

Stethoscope

A **stethoscope** is used to locate the source of engine and other noises. The stethoscope pickup is placed on the suspected component, and the stethoscope receptacles are placed in the technician's ears (**Figure 5-5**). Some sounds can be heard easily without using a listening device, but others are impossible to hear unless amplified, which is what a stethoscope does. It can also help you distinguish between normal and abnormal noise. The best results, however, are obtained with an electronic listening device. With this tool you can tune into the noise, which allows you to eliminate all other noises that might distract or mislead you.

Transaxle Removal and Installation Equipment

The engines of some FWD vehicles are removed by lifting them from the top. Others must be removed from the bottom and this requires special equipment. The required equipment varies with manufacturer and vehicle model; however, most accomplish the same thing.

To remove the engine from under the vehicle, the vehicle must be raised. A crane and/or support fixture

is used to hold the engine and transaxle assembly in place while the engine is being readied for removal. Then the engine is lowered onto an engine cradle. The cradle is similar to a floor jack and lowers the engine further so it can be rolled out from under the vehicle.

Often a transverse-mounted engine is removed with the transaxle. The transaxle is separated from the engine after it has been removed.

Ridge Reamer

After many miles of use, a ridge is formed at the top of the engine's cylinders. Because the top piston ring stops traveling before it reaches the top of the cylinder, a ridge of unworn metal is left. This ridge must be removed to push the pistons out of the block without damaging them during engine rebuilding. This ridge is removed with a **ridge reamer** (**Figure 5-6**). The tool is adjusted for the bore, inserted into it, and rotated with a wrench until the ridge is removed.

Ring Compressor

A **ring compressor** is used to install a piston into a cylinder bore. The compressor wraps around the rings to make their outside diameter smaller than the inside diameter of the bore. With the compressor tool adjusted properly, the piston assembly can be easily pushed into the bore without damaging the bore or piston.

Figure 5-5 A stethoscope.

Figure 5-6 A ridge reamer.

Figure 5-7 A piston ring compressor. *Reproduced under license from Snap-on Incorporated. All of the marks are marks of their owners.*

Figure 5-8 A piston ring compressor with a steel band and ratcheting pliers.

There are three basic types of ring compressors. One style has an adjustable band with a ratchet mechanism to tighten it around the piston (**Figure 5-7**). Another style uses ratcheting pliers to tighten a steel band around the piston (**Figure 5-8**). The bands are available in a variety of sizes. The third type has a single band that is wrinkled. The band is tightened by moving a lever. Once the rings are totally compressed into the piston, a thumbscrew is tightened to hold the band in position.

Ring Expander

To prevent damage to the piston rings during removal and installation, a **ring expander** should be used. To install a piston ring, the ring must be made large enough to fit over the piston. The rings fit into the jaws of the expander and the handle of the tool is squeezed to expand the ring (**Figure 5-9**). Expand the rings only to the point where they can fit over the piston. Using an expander prevents the possibility of cracking or distorting the rings while they are being expanded. The tool also helps to prevent cut fingers caused by the edges of the rings.

Ring Groove Cleaner

Before installing piston rings onto a piston, the ring grooves should be cleaned. The carbon and other debris that may be present in the back of the groove will not allow the rings to compress evenly and com-

Figure 5-9 A piston ring expander.

pletely into the grooves. Piston ring grooves are best cleaned with a **ring groove cleaner**. This tool is adjustable to fit the width and depth of the groove. Make sure it is properly adjusted before using it and make sure you do not damage the piston while cleaning it.

Dial Bore Indicator

Cylinder bore taper and out-of-roundness can be measured with a micrometer and a telescoping gauge. However, most shops use a **dial bore gauge**. This gauge typically consists of a handle, guide blocks, a lock, an indicator contact, and an indicator. They also come with extensions that make them adaptable to various size bores. As the dial bore gauge is moved inside the bore, the indicator will show any change in the bore's diameter.

Cylinder Hone and Deglazer

The proper surface finish on a cylinder wall acts as a reservoir for oil to lubricate the piston rings and prevent piston and ring scuffing. On most late-model engines, sleeves or inserts into the engine block provide this finish, and when damaged or worn, the sleeves are replaced. On other engines, the cylinder walls can be refurbished. Always refer to the manufacturer's recommendation before servicing cylinder walls. When the walls have minor problems, the bore can be honed. Honing sands the walls to remove imperfections. A **cylinder hone** usually consists of two or three stones. The hone rotates at a selected speed and is moved up and down the cylinder's bore. Honing oil flows over the stones and onto the cylinder wall to control the temperature and flush out any metallic and abrasive residue. The correct stones should be used to ensure that the finished walls have the correct surface finish. Honing stones are classified by grit size; typically, the lower the grit number, the coarser the stone.

Cylinder honing machines are available in manual and automatic models. The major advantage of the automatic type is that it allows the technician to dial in the exact crosshatch angle needed.

If the cylinder walls have surface conditions, taper, and out-of-roundness that are within acceptable limits, the walls only need to be deglazed. Combustion heat, engine oil, and piston movement combine to form a thin residue on the cylinder walls that is commonly called glaze.

Most cylinder deglazers or **glaze breakers** use an abrasive with about 220 or 280 grit. The glaze breaker is installed in a slow-moving electric drill or in a honing machine. Many deglazers use round stones that extend on coiled wire from the center shaft. This type deglazer may also be used to lightly hone the bore. Various sizes of resilient-based hone-type brushes are available for honing and deglazing.

When cylinder surfaces are badly worn or excessively scored or tapered, a **boring bar** is used to cut the cylinders for oversize pistons or sleeves. A boring bar leaves a pattern similar to uneven screw threads. Therefore, the bore should be honed to the correct finish after it has been bored.

Cam Bearing Driver Set

The camshaft is supported by several friction-type bearings, or bushings. They are designed as one piece and are typically pressed into the camshaft bore in the cylinder head or block; however, some overhead camshaft (OHC) engines use split bearings to support the camshaft. Camshaft bearings are normally replaced during engine rebuilding. Cam bearings are normally press fit into the block or head using a bushing driver and hammer.

V-Blocks

The various shafts in an engine must be straight and not distorted. Visually it is impossible to see any distortions unless the shaft is severely damaged. Warped or distorted shafts will cause many problems, including premature wear of the bearings they ride on. The best way to check a shaft is to place the ends of the shaft onto V-blocks. These blocks will support the shaft and allow you to rotate the shaft. Place the plunger of a dial indicator on the journals of the shaft and rotate the shaft. Any movement of the indicator's needle suggests a problem.

Valve and Valve Seat Resurfacing Equipment

Whenever the valves have been removed from the cylinder head, the valve heads and valve seats should be resurfaced. The most critical sealing surface in the

Figure 5-10 A valve grinding machine.

valvetrain is between the face of the valve and its seat in the cylinder head. Leakage between these surfaces reduces the engine's compression and power and can lead to valve burning. To ensure proper seating of the valve, the seat area on the valve face and seat must be the correct width, at the correct location, and concentric with the guide. These conditions are accomplished by renewing the surface of the valve face (**Figure 5-10**) and seat.

Valve and valve seat grinding or refacing is done by machining with a grinding stone or metal cutters to achieve a fresh, smooth surface on the valve faces and stem tips. Valve faces suffer from burning, pitting, and wear caused by opening and closing millions of times during the life of an engine. Valve stem tips wear because of friction from the rocker arms or actuators.

Valve Guide Repair Tools

The amount of valve guide wear can be measured with a ball gauge and micrometer. If wear or taper is excessive, the guide must be machined or replaced. If the original guide can be removed and a new one inserted, press out the old valve guide with a properly sized driver. Then install a new guide with a press and the same driver.

Some technicians knurl the old guide to restore the inside diameter dimension (ID) of a worn valve guide. Knurling raises the surface on the inside of the guide by plowing tiny furrows through the surface. This effectively decreases the ID of the guide. A burnisher is used to flatten the ridges and produce a proper-sized hole to restore the correct guide-to-stem clearance.

Reaming is often done to increase a guide's ID to accept an oversized valve stem or a guide insert. Some valve guide liners or inserts are not precut to length and the excess must be milled off before finishing.

Figure 5-11 A typical spring compressor for OHC valves.

Valve Spring Compressor

To remove the valves from a cylinder head, the valve spring assemblies must be removed. To do this, the valve spring must be compressed enough to remove the valve keepers, then the retainer. There are many types of **valve spring compressors**. Some are designed to allow valve spring removal while the cylinder head is still on the engine block. Other designs are only used when the cylinder head is removed.

The prybar-type compressor is used while the cylinder head is still mounted to the block. With the cylinder's piston at TDC, shop air is fed into the cylinder to hold the valve up and prevent it falling into the cylinder.

Some OHC engines require the use of a special spring compressor (**Figure 5-11**). Often these special tools can be used when the cylinder head is attached to the block and when it is on a bench. They bolt to the cylinder head and have a threaded plunger that fits onto the retainer. As the plunger is tightened down on the retainer, the spring compresses.

C-clamp-type spring compressors can only be used on cylinder heads after they have been removed (**Figure 5-12**). These are normally equipped with interchangeable jaws and can be pneumatically or manually operated. One end of the clamp is positioned on the valve head and the other on the valve's retainer. After the compressor is adjusted, it is activated to squeeze down on the spring. Once the spring is compressed, the valve keepers can be removed. Then the tension of the compressor is slowly released and the valve retainer and spring can be removed.

Valve Spring Tester

Before valve springs are reused, they should be checked to make sure they are within specifications. This checking should include their freestanding height and squareness. If those two dimensions are

Figure 5-12 A C-clamp valve spring compressor.

good, the spring should be checked with a **valve spring tester**. A valve spring tester checks each valve's open and close pressure. Correct close pressure guarantees a tight seal. The open pressure overcomes valvetrain inertia and closes the valve when it should close. The tester's gauge reflects the pressure of the spring when it is compressed to the installed or valve-closed height. Read the pressure on the tester and compare this reading to specifications. Any pressure outside the pressure range given in the specifications indicates the spring should be replaced.

Torque Angle Gauge

Most manufacturers recommend the torque-angle method for tightening cylinder head bolts, which requires the use of a **torque angle gauge**. Typically two steps are involved: Tighten the bolt to the specified torque, and then tighten the bolt an additional amount. The latter is expressed in degrees. To accurately measure the number of degrees added to the bolt, a torque angle gauge (**Figure 5-13**) is attached to the wrench. The additional tightening will stretch the

Figure 5-13 A torque angle gauge attached to the drive lug of a torque wrench.

bolt and produce a very reliable clamp load that is much higher than can be achieved just by torquing.

Oil Priming Tool

Prior to starting a freshly rebuilt engine, the oil pump must be primed. There are several ways to prelubricate, or prime, an engine. One method is to drive the oil pump with an electric drill. With some engines, it is possible to make a drive that can be chucked in an electric drill motor to engage the drive on the oil pump. Insert the fabricated oil pump drive extension into the oil pump through the distributor drive hole. To control oil splash, loosely set the valve cover(s) on the engine. After running the oil pump for several minutes, remove the valve cover and see whether there is any oil flow to the rocker arms. If oil reached the cylinder head, the engine's lubrication system is full of oil and is operating properly. If no oil reached the cylinder head, there is a problem either with the pump, with the alignment of an oil hole in a bearing, or perhaps with a plugged gallery.

Using a prelubricator (**Figure 5-14**), which consists of an oil reservoir attached to a continuous air supply, is the best method of prelubricating an engine without running it. When the reservoir is attached to the engine and the air pressure is turned on, the prelubricator will supply the engine's lubrication system with oil under pressure.

Figure 5-14 An engine preluber kit. Courtesy of SPX Service Solutions

Figure 5-15 Cooling system pressure tester.

Cooling System Pressure Tester

A cooling system pressure tester (**Figure 5-15**) contains a hand pump and a pressure gauge. A hose is connected from the hand pump to a special adapter that fits on the radiator filler neck. This tester is used to pressurize the cooling system and check for coolant leaks. Additional adapters are available to connect the tester to the radiator cap. With the tester connected to the radiator cap, the pressure relief action of the cap may be checked.

Coolant Hydrometer

A coolant **hydrometer** is used to check the amount of antifreeze in the coolant. This tester contains a pickup hose, a coolant reservoir, and a squeeze bulb. The pickup hose is placed in the radiator coolant. When the squeeze bulb is squeezed and released, coolant is drawn into the reservoir. As coolant enters the reservoir, a float moves upward with the coolant level. A pointer on the float indicates the freezing point of the coolant on a scale located on the reservoir housing.

Refractory Testers For many shops, the preferred way to check coolant is with a refractometer (**Figure 5-16**). This tester works on the principle that light bends as it passes through a liquid. A sample of the coolant is placed in the tester. As light passes through the sample of coolant, it bends and shines on a scale in the tester. A reading is taken at the point on the scale where there is a separation of light and dark. Most refractory coolant testers can also check the electrolyte in a battery.

Measuring pH Acids produced by bacteria and other contaminants can reduce the effectiveness of coolant. Some shops measure the pH of coolant to determine deterioration of the coolant. The pH is measured

Figure 5-16 A refractometer checks the condition of the engine's coolant.

by placing test strips or a digital pH tester into the coolant.

Coolant Recovery and Recycle System

A coolant recovery and recycle machine (**Figure 5-17**) typically can drain, recycle, fill, flush, and pressure

Figure 5-17 A coolant recycling machine that drains, back flushes, and fills the cooling system.

test a cooling system. Usually additives are mixed into the used coolant during recycling. These additives either bind to contaminants in the coolant so they can be easily removed, or they restore some of the chemical properties in the coolant.

ELECTRICAL/ELECTRONIC SYSTEM TOOLS

Electrical system service and diagnostic tools are discussed in the following paragraphs. This discussion does not cover all of the tools you may need; rather, these tools are the most commonly used by the service industry. Many automotive systems are electrically controlled and operated; therefore, these tools are also used in those systems. Details of when and how to use these tools are presented in Section 3 of this book, as well as in the sections that discuss the various other automotive systems.

Computer Memory Saver

Memory savers are an external power source used to maintain the memory circuits in electronic accessories and the engine, transmission, and body computers when the vehicle's battery is disconnected. The saver is plugged into the vehicle's cigar lighter outlet. It can be powered by a 9- or 12-volt battery (**Figure 5-18**).

Circuit Tester

Circuit testers (**Figure 5-19**) are used to check for voltage in an electrical circuit. A circuit tester, commonly called a **testlight**, looks like a stubby ice pick. Its handle is transparent and contains a light bulb. A probe extends from one end of the handle and a ground clip and wire from the other end. When the ground clip is attached to a good ground and the probe touched to a live connector, the bulb in the

Figure 5-18 A simple 9-volt memory saver.

Figure 5-19 Typical circuit tester, commonly called a testlight.

handle will light up. If the bulb does not light, voltage is not available at the connector.

WARNING!

Never use a 12 V testlight to diagnose components and wires in computer systems. The current draw of these testlights may damage the computer system components. High-impedance testlights are available for diagnosing computer systems.

A self-powered testlight is called a **continuity tester**. It is used on open circuits. It looks like a regular testlight but has a small internal battery. When the ground clip is attached to one end of the wire or circuit and the probe touched to the other end, the lamp will light if there is continuity in the circuit. If an open circuit exists, the light will not illuminate.

WARNING!

Do not use any type of testlight or circuit tester to diagnose automotive air bag systems. Use only the vehicle manufacturer's recommended equipment on these systems.

Voltmeter

A **voltmeter** has two leads: a red positive lead and a black negative lead. The red lead should be connected to the positive side of the circuit or component. The black should be connected to ground or to the nega-

tive side of the component. Voltmeters should be connected across the circuit being tested.

A voltmeter measures the voltage available at any point in an electrical system. A voltmeter can also be used to test voltage drop across an electrical circuit, component, switch, or connector. A voltmeter can also be used to check for proper circuit grounding.

Ohmmeter

An **ohmmeter** measures resistance to current flow in a circuit. In contrast to the voltmeter, which operates by the voltage available in the circuit, an ohmmeter is battery powered. The circuit being tested must have no power applied. If the power is on in the circuit, the ohmmeter will be damaged.

The two leads of the ohmmeter are placed across or in parallel with the circuit or component being tested. The red lead is placed on the positive side of the circuit and the black lead is placed on the negative side of the circuit. The meter sends current through the component and determines the amount of resistance based on the voltage dropped across the load. The scale of an ohmmeter reads from 0 to infinity (∞). A 0 reading means there is no resistance in the circuit and may indicate a short in a component that should show a specific resistance. An infinity reading indicates a number higher than the meter can measure, which usually indicates an open circuit.

Ammeter

An **ammeter** measures current flow in a circuit. Current is measured in amperes. Unlike the voltmeter and ohmmeter, the ammeter must be placed into the circuit or in series with the circuit being tested. Normally, this requires disconnecting a wire or connector from a component and connecting the ammeter between the wire or connector and the component. The red lead of the ammeter should always be connected to the side of the connector closest to the positive side of the battery and the black lead should be connected to the other side.

It is much easier to test current using an ammeter with an inductive pickup (**Figure 5-20**). The pickup clamps around the wire or cable being tested. The ammeter determines amperage based on the magnetic field created by the current flowing through the wire. This type of pickup eliminates the need to separate the circuit to insert the meter.

Volt/Ampere Tester

A volt/ampere tester (**VAT**), shown in **Figure 5-21**, is used to test batteries, starting systems, and charging systems. The tester contains a voltmeter, ammeter, and carbon pile. The carbon pile is a variable resistor.

Figure 5-20 An ammeter with an inductive pickup is called a current probe. Courtesy of SPX Service Solutions

Figure 5-21 The volt/amp tester checks batteries and the starting and charging systems.

When the tester is attached to the battery and turned on, the carbon pile draws current out of the battery. The ammeter will read the amount of current draw. The maximum current draw from the battery, with acceptable voltage, is compared to the rating of the battery to see if the battery is okay. A VAT also measures the current draw of the starter and current output from the charging system.

Multimeters

A **multimeter** is a must for diagnosing the individual components of an electrical system. Multimeters

Figure 5-22 Typical multifunctional, low-impedance multimeter.

have different names, depending on what they measure and how they function. A volt-ohm-milliammeter is referred to as a VOM or DVOM, if it is digital. A **digital multimeter (DMM)** can measure many more things than volts, ohms, and low current.

Most multimeters (**Figure 5-22**) measure direct current (dc) and alternating current (ac) amperes, volts, and ohms. More advanced multimeters may also measure diode continuity, frequency, temperature, engine speed, and dwell, and/or duty cycle.

Multimeters are available with either digital or analog displays. DMMs provide great accuracy by measuring volts, ohms, or amperes in tenths, hundredths, or thousandths of a unit. Several test ranges are usually provided for each of these functions. Some meters have multiple test ranges that must be manually selected; others are autoranging.

Analog meters use a sweeping needle against a scale to display readings and are not as precise as digital meters. Analog meters have low input impedance and should not be used on sensitive electronic circuits or components. Digital meters have high impedance and can be used on electronic circuits as well as electrical circuits.

Lab Scopes

An oscilloscope or **lab scope** is a visual voltmeter (**Figure 5-23**). A lab scope converts electrical signals to a visual image representing voltage changes over a specific period of time. This information is displayed in the form of a continuous voltage line called a **waveform** or **trace**. With a scope, precise measurement is possible. A scope displays any change in voltage as it occurs.

Figure 5-23 Two types of lab scopes.

An upward movement of the voltage trace on an oscilloscope indicates an increase in voltage, and a downward movement of this trace represents a decrease in voltage. As the voltage trace moves across an oscilloscope screen, it represents a specific length of time.

The size and clarity of the displayed waveform is dependent on the voltage scale and the time reference selected. Most scopes are equipped with controls that allow voltage and time interval selection. It is important when choosing the scales to remember that a scope displays voltage over time.

Dual-trace scopes can display two different waveform patterns at the same time. This type scope is especially important for diagnosing intermittent problems.

Most new lab scopes can display more than two waveforms and are hand-held units. Some scopes have an electronic library of known good signals, which allow technicians to compare what they see with what they should be seeing. Some also include wiring diagrams and additional diagnostic and testing information.

Graphing Multimeter

One of the latest trends in diagnostic tools is a graphing digital multimeter. These meters display readings over time, similar to a lab scope. The graph displays the minimum and maximum readings on a graph, as well as displaying the current reading (**Figure 5-24**). By observing the graph, a technician can detect any undesirable changes during the transition from a low reading to a high reading, or vice versa. These glitches are some of the more difficult problems to identify without a graphing meter or a lab scope.

Figure 5-24 The screen of a graphing multimeter. Reproduced under license from Snap-on Incorporated. All of the marks are marks of their owners.

Battery Hydrometer

On unsealed batteries, the specific gravity of the electrolyte can be measured to give a fairly good indication of the battery's state of charge. A hydrometer (**Figure 5-25**) is used to perform this test. A battery hydrometer consists of a glass tube or barrel, rubber bulb, rubber tube, and a glass float or hydrometer with a scale built into its upper stem. The glass tube encases the float and forms a reservoir for the test electrolyte. Squeezing the bulb pulls electrolyte into the reservoir.

When filled with test electrolyte, the hydrometer float bobs in the electrolyte. The depth to which the glass float sinks in test electrolyte indicates its relative weight compared to water. The reading is taken off the scale by sighting along the level of the electrolyte.

Figure 5-25 A hydrometer is used to measure the specific gravity of a battery's electrolyte.

WARNING!

Be careful not to allow the battery's electrolyte to drip on you or the vehicle. The electrolyte is a very strong acid and can burn your skin and damage the vehicle's paint.

Wire and Terminal Repair Tools

Many automotive electrical problems can be traced to faulty wiring. Loose or corroded terminals; frayed, broken, or oil-soaked wires; and faulty insulation are the most common causes.

Wires and connectors are often repaired or replaced. Sometimes an entire length of wire is replaced; other times only a section is. In either case, the wire must have the correct terminal or connector to work properly in the circuit. Wire cutters, stripping tools, terminal crimpers, and **connector picks** are the most commonly used tools for wire repair. Also, soldering equipment is used to provide the best electrical connection for a wire to another wire and for a wire to a connector.

Headlight Aimers

Headlights must be kept in adjustment to obtain maximum illumination. Sealed beams that are properly adjusted cover the correct range and afford the

driver the proper nighttime view. Headlights can be adjusted using headlamp-adjusting tools or by shining the lights on a chart. Headlight-aiming tools give the best results with the least amount of work. Many late-model vehicles have levels built into the headlamp assemblies that are used to correctly adjust the headlights.

Most headlight aimers use mirrors with split images, like split-image finders on some cameras, and spirit levels to determine exact adjustment. When using any headlight-aiming equipment, follow the instructions provided by the equipment manufacturer.

ENGINE PERFORMANCE TOOLS

Diagnostic and special tools for the air, fuel, ignition, emission, and engine-control systems are discussed in the following paragraphs. This discussion does not cover all of the tools you may need; rather, these tools are the most commonly used by the service industry. Some are also used when diagnosing or servicing the controls of other automotive systems. Details of when and how to use these tools are covered in Section 4 of this book, as well as in other sections where necessary.

Scan Tools

A **scan tool** (Figure 5-26) is a microprocessor designed to communicate with the vehicle's computer. Connected to the computer through diagnostic connectors, a scan tool can access diagnostic trouble codes (DTCs), run tests to check system operations, and monitor the activity of the system. Trouble codes and test results are displayed on a screen or printed out on the scanner printer.

Figure 5-26 A Genisys scan tool.

Figure 5-27 Various scan tool connectors for OBD-II systems.

The scan tool is connected to specific diagnostic connectors on the vehicle. Some manufacturers have one diagnostic connector. This connects the data wire from each computer to a specific terminal in this connector. Other manufacturers have several diagnostic connectors on each vehicle, and each of these connectors may be connected to one or more computers (**Figure 5-27**). The scan tool must be programmed for the model year, make of vehicle, and type of engine.

With OBD-II, the diagnostic connectors (commonly called data link connectors, or DLCs) are located in the same place on all vehicles. Also, any scan tool designed for OBD-II will work on all OBD-II systems; therefore, the need to have designated scan tools or cartridges is eliminated. Most OBD-II scan tools have the ability to store, or “freeze,” data during a road test (**Figure 5-28**) and then play back this data when the vehicle is returned to the shop.

There are many different scan tools available. Some are a combination of other diagnostic tools,

Figure 5-28 Using a scan tool during a road test. Courtesy of SPX Service Solutions

such as a lab scope and graphing multimeter. These may have the following capabilities:

- Retrieve DTCs.
- Monitor system operational data.
- Reprogram the vehicle's electronic control modules.
- Perform systems diagnostic tests.
- Display appropriate service information, including electrical diagrams.
- Display TSBs.
- Display troubleshooting instructions.
- Perform easy tool updating through a personal computer (PC).

Some scan tools work directly with a PC through uncabled communication links, such as Bluetooth. Others use a Personal Digital Assistant (PDA). These are small hand-held units that allow you to read DTCs, monitor the activity of sensors, and view inspection/maintenance system test results to quickly determine what service the vehicle requires. Most of these scan tools also have the ability to:

- Perform system and component tests.
- Report test results of monitored systems.
- Exchange files between a PC and a PDA.
- View and print files on a PC.
- Print DTC/freeze frame.
- Generate emissions reports.
- View IM/Mode 6 information.
- Display relative TSBs.
- Display full diagnostic code descriptions.
- Observe live sensor data.
- Update the scan tool as a manufacturer's interfaces change.

Engine Analyzers

When performing a complete engine performance analysis, an engine analyzer is used (**Figure 5-29**). An engine analyzer houses all of the necessary test equipment. With an engine analyzer, you can perform tests on the battery, starting system, charging system, primary and secondary ignition circuits, electronic control systems, fuel system, emissions system, and engine assembly. The analyzer is connected to these systems by a variety of leads, inductive clamps, probes, and connectors. The data received from these connections is processed by several computers within the analyzer.

Most engine analyzers have both manual and automatic test modes. In the manual modes, any

Figure 5-29 An engine analyzer.

single test, such as cylinder compression or generator output, can be performed. When the automatic test mode is selected, specific tests are automatically performed in a specific sequence.

The analyzer may compare the test results to the vehicle manufacturer's specifications. When the test series is completed, the analyzer prints a summary report. Many analyzers also provide diagnostic assistance for the problems indicated by their measurements.

Fuel Pressure Gauge

A fuel **pressure gauge** is essential for diagnosing fuel injection systems (**Figure 5-30**). These systems rely on very high fuel pressures, from 35 to 70 psi. A drop in fuel pressure reduces the amount of fuel delivered to the injectors and results in a lean air-fuel mixture.

A fuel pressure gauge is used to check the discharge pressure of fuel pumps, the regulated pressure of fuel injection systems, and injector pressure drop. This test can identify faulty pumps, regulators, or injectors and can identify restrictions present in the fuel delivery system. Restrictions are typically caused by a dirty fuel filter, collapsed hoses, or damaged fuel lines.

Some fuel pressure gauges also have a valve and outlet hose for testing fuel pump discharge volume.

Figure 5-30 A fuel pressure gauge and adapters.

The manufacturer's specification for discharge volume is given as a number of pints or liters of fuel that should be delivered in a certain number of seconds.

CAUTION!

While testing fuel pressure, be careful not to spill gasoline. Gasoline spills may cause explosions and fires, resulting in serious personal injury and property damage.

Injector Balance Tester

The injector balance tester (**Figure 5-31**) is used to test the injectors in a port fuel injected engine for proper operation. A fuel pressure gauge is also used during the injector balance test. The injector balance tester contains a timing circuit, and some injector balance testers have an off-on switch. A pair of leads on the tester must be connected to the battery with the correct polarity. The injector terminals are

Figure 5-31 A fuel injection balance tester.

disconnected, and a second double lead on the tester is attached to the injector terminals.

The fuel pressure gauge is connected to the Schrader valve on the fuel rail, and the ignition switch should be cycled two or three times until the specified fuel pressure is indicated on the pressure gauge. When the tester push button is depressed, the tester energizes the injector winding for a specific length of time, and the technician records the pressure decrease on the fuel pressure gauge. This procedure is repeated on each injector.

If the pressure drops very little, or if there is no pressure drop, the injector's orifice is restricted or the injector is faulty. If there is an excessive amount of pressure drop, the injector plunger is sticking open. Sticking injector plungers may result in a rich air-fuel mixture.

WARNING!

Electronic fuel injection systems are pressurized, and these systems require depressurizing prior to fuel pressure testing and other service procedures.

Injector Circuit Testlight

A special testlight called a **noid light** can be used to determine if a fuel injector is receiving its proper voltage pulse from the computer (**Figure 5-32**). The wiring harness connector is disconnected from the injector and the noid light is plugged into the connector. After disabling the ignition to prevent starting, the engine is turned over by the starter motor. The noid light will flash rapidly if the voltage signal is present.

Figure 5-32 A set of noid lights and a test spark plug.

No flash usually indicates an open in the power feed or ground circuit to the injector.

Fuel Injector Cleaners

Fuel injectors spray a certain amount of fuel into the intake system. If the fuel pressure is low, not enough fuel will be sprayed. Low pressure may also occur if the fuel injector is dirty. Normally, clogged injectors are the result of inconsistencies in gasoline detergent levels and the high sulfur content of gasoline. When these sensitive fuel injectors become partially clogged, fuel flow is restricted. Spray patterns are altered, causing poor performance and reduced fuel economy.

The solution to a sulfated and/or plugged fuel injector is to clean it, not replace it. There are two kinds of fuel injector cleaners. One is a pressure tank. A mixture of solvent and unleaded gasoline is placed in the tank, following the manufacturer's instructions for mixing, quantity, and safe handling. The vehicle's fuel pump is disabled and, on some vehicles, the fuel line must be blocked between the pressure regulator and the return line. Then, the hose on the pressure tank is connected to the service port in the fuel system. The inline valve is then partially opened and the engine is started. It should run at approximately 2,000 rpm for about 10 minutes to clean the injectors thoroughly.

An alternative to the pressure tank is a pressurized canister in which the solvent solution is premixed. Use of the canister-type cleaner is similar to this procedure but does not require mixing or pumping. The canister is connected to the injection system's servicing fitting, and the valve on the canister is opened. The engine is started and allowed to run until it dies. Then, the canister is discarded.

Fuel Line Tools

Many vehicles are equipped with quick-connect line couplers. These work well to seal the connection but are nearly impossible to disconnect if the correct tools are not used. There is a variety of quick-connect fittings and tools (**Figure 5-33**).

Pinch-Off Pliers

The need to pinch off a rubber hose is common during diagnostics and service. Special pliers are designed to do this without damaging the hose (**Figure 5-34**). These pliers are much like vise-grip pliers in that they hold their position until they are released. The jaws of the pliers are flat and close in a parallel motion. Both of these features prevent damage to the hose.

Vacuum Gauge

Measuring intake manifold vacuum is another way to diagnose the condition of an engine. Manifold

Figure 5-33 Various fuel line disconnect tools.

Figure 5-34 Pinch-off pliers closing off a vacuum hose.

vacuum is tested with a vacuum gauge. **Vacuum** is formed on a piston's intake stroke. As the piston moves down, it lowers the pressure of the air in the cylinder—if the cylinder is sealed. This lower cylinder pressure is called engine vacuum. If there is a leak, atmospheric pressure will force air into the cylinder and the resultant pressure will not be as low. The reason atmospheric pressure enters is simply that whenever there is a low and high pressure, the high pressure always moves toward the low pressure. Vacuum is measured in inches of mercury (in. Hg) and in kilopascals (kPa).

To measure vacuum, a flexible hose on the vacuum gauge (**Figure 5-35**) is connected to a source of manifold vacuum, either on the manifold or at a point

Figure 5-35 A vacuum/pressure tester used to measure engine vacuum.

below the throttle plates. The test is made with the engine cranking or running. A good vacuum reading is typically at least 16 in. Hg. However, a reading of 15 to 20 in. Hg (50 to 65 kPa) is normally acceptable. Since the intake stroke of each cylinder occurs at a different time, the production of vacuum occurs in pulses. If the amount of vacuum produced by each cylinder is the same, the vacuum gauge will show a steady reading. If one or more cylinders are producing different amounts of vacuum, the gauge will show a fluctuating reading.

Vacuum Pump

There are many vacuum-operated devices and vacuum switches on cars. These devices use engine vacuum to cause a mechanical action or to switch something on or off. The tool used to test vacuum-actuated components is the vacuum pump. There are two types of vacuum pumps: an electrical-operated pump and a hand-held pump. The hand-held pump is most often used for diagnostics (**Figure 5-36**). A hand-held vacuum pump consists of a hand pump, a vacuum gauge, and a length of rubber hose used to attach the pump to the component being tested. Tests with the vacuum pump can usually be performed without removing the component from the vehicle.

When the handles of the pump are squeezed together, a piston inside the pump body draws air out of the component being tested. The partial vacuum created by the pump is registered on the pump's vacuum gauge. While forming a vacuum in a component, watch the action of the component. The vacuum level needed to actuate a given component should be compared to the specifications given in the factory service manual.

Figure 5-36 Typical hand-operated vacuum pump with accessories.

The vacuum pump is also used to locate vacuum leaks by connecting the vacuum pump to a suspect vacuum hose or component and applying vacuum. If the needle on the vacuum gauge begins to drop after the vacuum is applied, a leak exists somewhere in the system.

Vacuum Leak Detector

A vacuum or compression leak might be revealed by a compression check, a cylinder leakage test, or a manifold vacuum test. However, finding the location of the leak can often be very difficult.

A simple, but time-consuming, way to find leaks in a vacuum system is to check each component and vacuum hose with a vacuum pump. Simply apply vacuum to the suspected area and watch the gauge for any loss of vacuum. A good vacuum component holds the vacuum applied to it.

Another method of leak detection is done by using an ultrasonic leak detector. Air rushing through a vacuum leak creates a high-frequency sound higher than the range of human hearing. An ultrasonic leak detector is designed to hear the frequencies of the leak. When the tool is passed over a leak, the detector responds to the high-frequency sound by emitting a warning beep. Some detectors also have a series of light emitting diodes (LEDs) that light up as the frequencies are received. The closer the detector is moved to the leak, the more LEDs light up or the faster the beeping occurs, allowing the technician to zero in on the leak. An ultrasonic leak detector can sense leaks as small as 1/500 inch and accurately locate the leak to within 1/16 inch.

Tachometer

A **tachometer** is used to measure engine speed. Like other meters, tachometers are available in analog and

digital types. Digital meters are the most common. Tachometers are connected to the ignition system to monitor ignition pulses, which are then converted to engine speed by the meter.

Several types of inductive pickup tachometers that simplify rpm testing are available. An inductive tachometer simply clamps over the number 1 spark plug wire. The digital display gives the engine rpm, based on the magnetic pulses created by the secondary voltage in the wire. This type of tachometer is suitable for distributorless ignition systems.

Timing Light

A **timing light** (Figure 5-37) is used to check ignition timing. The timing light is connected to the battery terminals and has an inductive clamp that fits over the number 1 spark plug wire. While the engine is running, the timing light emits a beam of light each time the spark plug fires. Many timing lights have a timing advance knob that may be used to check spark advance. Some timing lights electronically measure timing advance as the engine rpm is increased and displays it on an LED display.

Spark Tester

A **spark tester** (see Figure 5-32) is a fake spark plug. The tester is constructed like a spark plug but does not have a ground electrode. In place of the electrode

Figure 5-37 A digital timing light. Courtesy of SPX Service Solutions

there is a grounding clamp. Using test spark plugs is an easy way to determine if the ignition problem is caused by something in the primary or secondary circuit.

The spark tester is inserted in the spark plug end of an ignition cable. When the engine is cranked, a spark should be seen from the tester to a ground. Experience with these testers will also help you determine the intensity of the spark.

Logic Probes

In some circuits, pulsed or digital signals pass through the wires. These on-off digital signals either carry information or provide power to drive a component. Many sensors, used in a computer-controlled circuit, send digital information back to the computer. To check the continuity of the wires that carry digital signals, a logic probe can be used.

A **logic probe** is similar in appearance to a test-light. It contains three different-colored LEDs. A red LED lights when there is high voltage at the point being probed. A green LED lights to indicate low voltage. A yellow LED indicates the presence of a voltage pulse. The logic probe is powered by the circuit and reflects only the activity at the point being probed. When the probe's test leads are attached to a circuit, the LEDs display the activity.

If a digital signal is present, the yellow LED turns on. When there is no signal, the LED is off. If voltage is present, the red or green LEDs will light, depending on the amount of voltage. When there is a digital signal and the voltage cycles from low to high, the yellow LED will be lit and the red and green LEDs will cycle, indicating a change in the voltage.

Sensor Tools

Oxygen sensors are replaced as part of the preventive maintenance program and when they are faulty. Because they are shaped much like a spark plug with wires or a connector coming out of the top, ordinary sockets do not fit well. For this reason, tool manufacturers provide special sockets for these sensors (**Figure 5-38**).

Special sockets are also available for other sending units and sensors.

Static Strap

Because electronic components are sensitive to voltage, static electricity can destroy them. Static straps are available for technicians to wear while working on or around electronic components. These straps typically are worn around a wrist and connected to a known good ground on the vehicle. The straps send all static electricity to the ground of the vehicle,

Figure 5-38 A heated oxygen sensor socket.
Courtesy of SPX Service Solutions

Figure 5-39 A hand-held digital infrared temperature gauge.

thereby eliminating the chance of this electricity going to the electronic components.

Pyrometers

The converter should be checked for its ability to convert CO and HC into CO₂ and water by doing a delta temperature test. To conduct this test, use a hand-held digital **pyrometer** (**Figure 5-39**). By touching the pyrometer probe or placing it near to the exhaust pipe just ahead of and just behind the converter, there should be an increase of at least 100°F or 8% above the inlet temperature reading as the exhaust gases pass through the converter. If the outlet temperature is the same or lower, nothing is happening inside the converter. A pyrometer can also be used to measure the temperature of the coolant at various stages of its travel.

Spark Plug Sockets

Special sockets are available for the installation and removal of spark plugs (**Figure 5-40**). These sockets are deep sockets with a hex nut drive at the end to

Figure 5-40 A spark plug socket. Courtesy of Honeywell International Inc.

allow a technician to turn them with a ratchet or an open-end wrench. The sockets are available in the common sizes of spark plugs (5/8-inch, 9/16-inch, and 13/16-inch) and have a 3/8-inch drive. The socket is built with a rubber sleeve that surrounds the insulator part of the spark plug to prevent cracking or other damage to the plug while it is being removed or installed.

Exhaust Analyzers

Federal laws require that new cars and light trucks meet specific emissions levels. State governments have also passed laws requiring that owners maintain their vehicles so that the emissions remain below an acceptable level. Most states require an annual emissions inspection to meet that goal. Many shops have an exhaust analyzer for inspection purposes.

Exhaust analyzers (**Figure 5-41**) are also very valuable diagnostic tools. By looking at the quality of an engine's exhaust, a technician is able to look at the engine's combustion process and the efficiency of the vehicle's emission controls. Any defect will cause emission levels to increase. The amount and type of change is considered during diagnostics.

Exhaust analyzers measure the amount of HC and CO in the exhaust. HC is measured in parts per mil-

Figure 5-41 A five-gas exhaust analyzer.

lion (ppm) or grams per mile (g/mi) and CO is measured as a percent of the total exhaust. In addition to measuring HC and CO levels, an exhaust analyzer also monitors CO₂ and O₂ levels. Many exhaust analyzers also measure a fifth gas (**Figure 5-42**), oxides of nitrogen (NO_x).

By measuring NO_x, CO₂, and O₂, in addition to HC and CO, a technician gets a better look at the engine's efficiency. There is a desired relationship among the

Figure 5-42 A "MicroGas" five-gas exhaust analyzer.

five gases. Any deviation from this relationship can be used to diagnose a driveability problem.

Chassis Dynamometer

A chassis **dynamometer**, commonly called a dyno, is used to simulate a road test. A vehicle can be driven through a wide assortment of operating conditions without leaving the shop. Because the vehicle is stationary, test equipment can be connected and monitored while the vehicle is driven under various loads. This is extremely valuable when diagnosing a problem. A chassis dyno can also be used for performance tuning.

The vehicle's drive wheels are positioned on large rollers. The electronically controlled rollers offer rotational resistance to simulate the various loads a vehicle may face.

Some performance shops have an engine dynamometer that directly measures the output from an engine. A chassis dynamometer measures the engine's output after it has passed through the driveline.

Hybrid Tools

A hybrid vehicle is an automobile and as such is subject to many of the same problems as a conventional vehicle. Most systems in a hybrid vehicle are diagnosed in the same way as well. However, a hybrid vehicle has unique systems that require special procedures and test equipment. It is imperative to have good information before attempting to diagnose these vehicles. Also, make sure you follow all test procedures precisely as they are given.

Gloves Always wear safety gloves when working on or around the high-voltage systems. These gloves must be class "0" rubber insulating gloves (**Figure 5-43**), rated at 1,000 volts (these are commonly called "**lineman's gloves**"). Also, to protect the integrity of

Figure 5-43 A pair of lineman's gloves.

the insulating gloves, as well as you, wear leather gloves over the insulating gloves while doing a service.

CAUTION!

The condition of the gloves must be checked before each use. Make sure there are no tears or signs of wear. Electrons are very small and can enter through the smallest of holes in your gloves. To check the condition of the gloves, blow enough air into each one so they balloon out. Then fold the open end over to seal the air in. Continue to slowly fold that end of the glove toward the fingers. This will compress the air. If the glove continues to balloon as the air is compressed, it has no leaks. If any air leaks out, the glove should be discarded. All gloves, new and old, should be checked before they are used.

Test Equipment An important diagnostic tool is a DMM. However, this is not the same DMM used on a conventional vehicle. The meter used on hybrids (and EVs and FCEVs) should be classified as a category III meter. There are basically four categories for low-voltage electrical meters, each built for specific purposes and to meet certain standards. Low voltage, in this case, means voltages less than 1,000 volts. The categories define how safe a meter is when measuring certain circuits. The standards for the various categories are defined by the American National Standards Institute (ANSI), the International Electrotechnical Commission (IEC), and the Canadian Standards Association (CSA). A CAT III meter (**Figure 5-44**) is required for testing hybrid vehicles because of the high voltages, three-phase current, and the potential for high transient voltages. **Transient voltages** are voltage surges or spikes that occur in AC circuits. To be safe, you should have a CAT III 1000 V meter. A meter's voltage rating reflects its ability to withstand transient voltages. Therefore, a CAT III 1000 V meter offers much more protection than a CAT III meter rated at 600 volts.

Figure 5-44 Only meters with this symbol should be used on the high-voltage systems in a hybrid vehicle.

WARNING!

Always follow the test procedures defined by the manufacturers when using their equipment.

Another important tool is an **insulation resistance tester**. These can check for voltage leakage through the insulation of the high-voltage cables. Obviously no leakage is desired and any leakage can cause a safety hazard as well as damage to the vehicle. Minor leakage can also cause hybrid system-related drivability problems. This meter is not one commonly used by automotive technicians but should be for anyone who might service a damaged hybrid vehicle, such as doing body repair. This should also be a CAT III meter and may be capable of checking resistance and voltage of circuits like a DMM.

To measure insulation resistance, system voltage is selected at the meter and the probes placed at their test position. The meter will display the voltage it detects. Normally, resistance readings are taken with the circuit de-energized unless you are checking the effectiveness of the cable or wire insulation. In this case, the meter is measuring the insulation's effectiveness and not its resistance.

The probes for the meters should have safety ridges or finger positioners. These help prevent physical contact between your fingertips and the meter's test leads.

TRANSMISSION AND DRIVELINE TOOLS

The repair and diagnostic tools for manual and automatic transmissions, as well as those required for driveline service, are discussed in the following paragraphs. This discussion does not cover all of the tools you may need; rather, these tools are the most commonly used by the service industry. Details of when and how to use these tools are covered in Sections 5 and 6 of this book.

Transaxle Removal and Installation Equipment

The removal and replacement (R&R) of transaxles mounted to transversely mounted engines may require different tools than those needed to remove a transmission from a RWD vehicle. Make sure you follow the manufacturer's instructions before attempting to remove the engine and/or transaxle from a FWD vehicle.

To remove the engine and transmission from under the vehicle, the vehicle must be raised. A crane and/or support fixture is used to hold the engine and transaxle assembly in place while the assembly is being readied for removal. When everything is set for removal of the assembly, the crane is used to lower the assembly onto a cradle. The cradle is similar to a hydraulic floor jack and is used to lower the assembly further so it can be rolled out from under the vehicle. The transaxle can be separated from the engine once it has been removed from the vehicle.

When the transaxle is removed as a single unit, the engine must be supported while it is in the vehicle before, during, and after transaxle removal. Special fixtures (**Figure 5-45**) mount to the vehicle's upper frame or suspension parts. These supports have a bracket that is attached to the engine. With the bracket in place, the engine's weight is on the support fixture and the transmission can be removed.

Transmission/Transaxle Holding Fixtures

Special holding fixtures should be used to support the transmission or transaxle after it has been removed from the vehicle (**Figure 5-46**). These holding fixtures may be stand-alone units or may be bench mounted.

Figure 5-45 An engine support is used to hold the engine in place while the transaxle is removed on many FWD vehicles. *Courtesy of SPX Service Solutions*

Figure 5-46 A transmission holding fixture.

Figure 5-47 A typical transmission jack.

They allow the transmission to be easily repositioned during repair work.

Transmission Jack

A transmission jack (**Figure 5-47**) is designed to help you while removing a transmission from under the vehicle. The weight of the transmission makes it difficult and unsafe to remove it without much assistance and/or a transmission jack. These jacks fit under the transmission and are usually equipped with hold-down chains, which are used to secure the transmission to the jack. The transmission's weight rests on the jack's saddle.

Transmission jacks are available in two basic styles. One is used when the vehicle is raised by a hydraulic jack and sitting on jack stands. The other style is used when the vehicle is raised on a lift.

Axle Pullers

Axle pullers are used to pull rear axles in RWD vehicles. Most rear axle pullers are slide hammer type.

Special Tool Sets

Vehicle manufacturers and specialty tool companies work closely together to design and manufacture special tools required to repair transmissions. Most of these special tools are listed in the appropriate service manuals and are part of each manufacturer's "essential tool kit."

Figure 5-48 A clutch alignment tool set with various sizes of pilots, adapters, and alignment cones. *Courtesy of SPX Service Solutions*

Clutch Alignment Tool

To keep the clutch disc centered on the flywheel while assembling the clutch, a clutch alignment tool is used. The tool is inserted through the input shaft opening of the pressure plate and is passed through the clutch disc. The tool then is inserted into the pilot bushing or bearing. The outside diameter (OD) of the alignment tool that goes into the pilot must be only slightly smaller than the ID of the pilot bushing. The OD of the tool that holds the disc in place must likewise be only slightly smaller than the ID of the disc's splined bore. The effectiveness of this tool depends on its diameter, so it is best to have various sizes of clutch alignment tools (**Figure 5-48**).

Clutch Pilot Bearing/Bushing Puller/Installer

To remove and install a clutch pilot bearing or bushing, special tools are needed. These tools not only make the job easier but also prevent damage to the bore in the flywheel.

Universal Joint Tools

Although servicing universal joints can be done with hand tools and a vise, many technicians prefer the use of specifically designed tools. One such tool is a C-clamp modified to include a bore that allows the joint's caps to slide in while tightening the clamp over an assembled joint to remove it (**Figure 5-49**). Other

Figure 5-49 A universal joint bearing press with adapters. *Reproduced under license from Snap-on Incorporated. All of the marks are marks of their owners.*

Figure 5-50 An angle gauge is used to check the angle of a drive shaft. *Reproduced under license from Snap-on Incorporated. All of the marks are marks of their owners.*

tools are the various drivers used with a press to press the joint in and out of its yoke.

Drive Shaft Angle Gauge

Critical to the durability of universal joints and vibration-free vehicle operation is the angle of the drive shaft. The angle of the drive shaft at the transmission should equal its angle at the drive axle. There are many ways to measure the angle; one way involves the use of an **inclinometer** or drive shaft angle gauge (Figure 5-50).

Hydraulic Pressure Gauge Set

A common diagnostic tool for automatic transmissions is a hydraulic pressure gauge (Figure 5-51). A pressure gauge measures pressure in pounds per square inch (psi) and/or kilopascals (kPa). The gauge is normally part of a kit that contains various fittings and adapters.

Figure 5-51 Pressure gauges are used to diagnose automatic transmissions and power steering systems.

SUSPENSION AND STEERING TOOLS

Suspension and steering repair and diagnostic tools as well as wheel alignment tools and equipment are discussed in the following paragraphs. This discussion does not cover all of the tools you may need; rather, these tools are the most commonly used by the service industry. Details of when and how to use these tools are covered in Section 7 of this book.

Tire Tread Depth Gauge

A tire tread depth gauge measures tire tread depth. This measurement should be taken at three or four locations around the tire's circumference to obtain an average tread depth. This gauge is used to determine the remaining life of a tire as well as for comparing wear of one tire to the other tires. It is also used when making tire warranty adjustments.

Power Steering Pressure Gauge

A power steering pressure gauge is used to test the power steering pump pressure. This test is also important when checking hydraulic boost brake systems. Because the power steering pump delivers extremely high pressure during this test, the recommended procedure in the vehicle manufacturer's service manual must be followed.

A pressure gauge with a shutoff valve is installed between the pump and the steering gear. Adapters are used to make good connections with the vehicle's power steering system.

Control Arm Bushing Tools

A variety of control arm bushing tools are available to remove and replace control arm bushings. Old bushings are pressed out of the control arm. A C-clamp tool can be used to remove the bushing. The C-clamp is installed over the bushing. An adapter is selected to fit on the bushing and push the bushing through the control arm. Turning the handle on the C-clamp pushes the bushing out of the control arm.

New bushings can be installed by driving or pressing them in place. Adapters are available for the C-clamp tool to install the new bushings. After the correct adapters are selected, position the bushing and tool on the control arm. Turning the C-clamp handle pushes the bushing into the control arm.

Tie-Rod End and Ball Joint Puller

Some car manufacturers recommend a tie-rod end and ball joint puller to remove tie-rod ends and pull ball joint studs from the steering knuckle.

Ball joint removal and pressing tools are designed to remove and replace pressed-in ball joints on front

Figure 5-52 A ball joint removal tool.

suspension systems (**Figure 5-52**). Often these tools are used in conjunction with a hydraulic press. The size of the removal and pressing tool must match the size of the ball joint.

Some ball joints are riveted to the control arm and the rivets are drilled out for removal.

Front Bearing Hub Tool

Front bearing hub tools are designed to remove and install front wheel bearings on FWD cars. These bearing hub tools are usually designed for a specific make of vehicle and the correct tools must be used for each application. Failure to do so may result in damage to the steering knuckle or hub. Also, the use of the wrong tool will waste quite a bit of your time.

Pitman Arm Puller

A pitman arm puller is a heavy-duty puller designed to remove the pitman arm from the pitman shaft (**Figure 5-53**). These pullers can also be used to separate tie-rod ends and ball joints.

Tie-Rod Sleeve-Adjusting Tool

A tie-rod sleeve-adjusting tool (**Figure 5-54**) is required to rotate the tie-rod sleeves and perform some front wheel adjustments. Never use anything except a tie-rod adjusting tool to adjust the tie-rod sleeves. Tools such as pipe wrenches will damage the sleeves.

Figure 5-53 A pitman arm puller is designed to remove the pitman arm from the pitman shaft. *Courtesy of SPX Service Solutions*

Figure 5-54 A tie-rod sleeve-adjusting tool. *Courtesy of SPX Service Solutions*

Steering Column Special Tool Set

A wheel puller is used to remove the steering wheel from its shaft. Mount the puller over the wheel's hub after the horn button and air bag have been removed. Make sure you follow the recommendations exactly for air bag module removal. Screw the bolts into the threaded bores in the steering wheel. Then tighten the puller's center bolt against the steering wheel shaft until the steering wheel is free.

Special tools are also required to service the lock mechanism and ignition switch.

Shock Absorber Tools

Often shock absorbers can be removed with regular hand tools, but there are times when special tools may be necessary. The shocks are under the vehicle and are subject to dirt and moisture, which may make it difficult to loosen the mounting nut from the stud of the shock. Wrenches are available to hold the stud while attempting to loosen the nut. There are also tools for pneumatic chisels that help to work off the nut.

Spring/Strut Compressor Tool

Many types of coil spring compressor tools are available to the automotive service industry. These tools are designed to compress the coil spring and hold it in the compressed position while removing the strut from the coil spring (**Figure 5-55**), removing the spring from a short-long arm (SLA) suspension, or performing other suspension work. Various types of spring compressor tools are required on different types of front suspension systems.

One type of spring compressor uses a threaded compression rod that fits through two plates, an upper and lower ball nut, a thrust washer, and a forcing nut. The two plates are positioned at either end of the spring. The compression rod fits through the plates with a ball nut at either end. The upper ball nut is pinned to the rod. The thrust washer and forcing

Figure 5-55 A spring compressor for a strut suspension.

nut are threaded onto the end of the rod. Turning the forcing nut draws the two plates together and compresses the spring.

There is a tremendous amount of energy in a compressed coil spring. Never disconnect any suspension component that will suddenly release this tension. This action could result in serious personal injury and vehicle or property damage.

Power Steering Pump Pulley Special Tool Set

When a power steering pump pulley must be replaced, it should never be hammered off or on. Doing so will cause internal damage to the pump. Normally the pulley can be removed with a gear puller, although special pullers are available. To install a pulley, a special tool is used to press the pulley on without a press or the need to drive the pulley in place.

Brake Pedal Depressor

A brake pedal depressor must be installed between the front seat and the brake pedal to apply the brakes

Figure 5-56 The technician is installing a brake pedal depressor; also note that a steering wheel lock is in place.

while checking some front wheel alignment angles to prevent the vehicle from moving (**Figure 5-56**).

Wheel Alignment Equipment—Four Wheel

Many automotive shops are equipped with a computerized four-wheel alignment machine (**Figure 5-57**) that can check all front- and rear-wheel alignment angles quickly and accurately.

After vehicle information is keyed into the machine and the wheel units are installed, the machine must be compensated for wheel runout. When compensation is complete, alignment measurements are instantly displayed. Also displayed are the specifications for that vehicle. In addition to the normal alignment specifications, the screen may display asymmetric tolerances, different left- and right-side specifications, and cross specifications. (A difference is allowed between left and right sides.) Graphics and text on the screen show the technician where and

Figure 5-57 A computerized four-wheel alignment setup. Courtesy of RTI Technologies, Inc.

how to make adjustments. As the adjustments are made on the vehicle, the technician can observe the center block slide toward the target. When the block aligns with the target, the adjustment is within half the specified tolerance.

Tire Changer

Tire changers are used to demount and mount tires. A wide variety of tire changers are available, and each one has somewhat different operating procedures. Always follow the procedure in the equipment operator's manual and the directions provided by your instructor.

Wheel Balancer—Electronic Type

The most commonly used wheel balancer requires that the tire/wheel assembly be taken off and mounted on the balancer's spindle (**Figure 5-58**). Weights are added to balance the tire/wheel assembly. The wheel assembly is rotated at high speed and the machine indicates the amount of weight to be added and the location where the weights should be placed.

Several electronic dynamic/static balancer units are available that permit balancing while the wheel and tire are on the vehicle. Often a strobe light flashes at the heavy point of the tire and wheel assembly.

Figure 5-58 An electronic wheel balancer.

Figure 5-59 Wheel weight pliers.

Wheel Weight Pliers

Wheel weight pliers are actually combination tools designed to install and remove clip-on lead wheel weights (**Figure 5-59**). The jaws of the pliers are designed to hook into a hole in the weight's bracket. The pliers are then moved toward the outside of the wheel and the weight is pried off. On one side of the pliers is a plastic hammer head used to tap the weights onto the rim.

BRAKE SYSTEM TOOLS

The repair and diagnostic tools for brake service are discussed in the following paragraphs. This discussion does not cover all of the tools you may need; rather, these tools are the most commonly used by the service industry. Details of when and how to use these tools are presented in Section 8 of this book.

Cleaning Equipment and Containment Systems

Equipment should be used to safely contain asbestos while doing brake work. A negative-pressure enclosure and high-efficiency particulate air (HEPA) vacuum system allow you to clean and inspect brake assemblies while preventing the release of asbestos fibers into the air. A vacuum pump and a HEPA filter keep the enclosure under negative pressure as work is done.

Low-pressure wet cleaning systems wash dirt from the brake assembly and catch the contaminated cleaning agent in a basin. This system uses water mixed with an organic solvent or wetting agent. The brake assembly is gently flooded to prevent any asbestos-containing brake dust from becoming airborne.

Figure 5-60 Brake spring pliers.

Holddown Spring and Return Spring Tools

Brake shoe return springs used on drum brakes are very strong and require special tools for removal and installation. Most return spring tools have special sockets and hooks to release and install the spring ends. Some are built like pliers (**Figure 5-60**).

Holddown springs for brake shoes are much lighter than return springs, and many such springs can be released and installed by hand. A holddown spring tool (**Figure 5-61**) looks like a cross between a screwdriver and a nut driver. A specially shaped end grips and rotates the spring retaining washer.

Figure 5-61 A holddown spring compressor tool.

Boot Drivers, Rings, and Pliers

Dust boots attach between the caliper bodies and pistons of disc brakes to keep dirt and moisture out of the caliper bores. A special driver is used to install a dust boot with a metal ring that fits tightly on the caliper body. The circular driver is centered on the boot placed against the caliper and then hit with a hammer to drive the boot into place. Other kinds of dust boots fit into a groove in the caliper bore before the piston is installed. Special rings or pliers are then needed to expand the opening in the dust boot and let the piston slide through it for installation.

Caliper Piston Removal Tools

A caliper piston can usually be slid or twisted out of its bore by hand. Rust and corrosion (especially where road salt is used in the winter) can make piston removal difficult. One simple tool that will help with the job is a set of special pliers that grips the inside of the piston and lets you move it by hand with more force. These pliers work well on pistons that are only mildly stuck.

For a severely stuck caliper piston, a hydraulic piston remover can be used. This tool requires that the caliper be removed from the car and installed in a holding fixture. A hydraulic line is connected to the caliper inlet and a hand-operated pump is used to apply up to 1,000 psi of pressure to loosen the piston. Because of the danger of spraying brake fluid, always wear eye protection when using this equipment.

Drum Brake Adjusting Tools

Although almost all drum brakes built during the past 30 years have some kind of self-adjuster, the brake shoes still require an initial adjustment after they are installed. The star wheel adjusters of many drum brakes can be adjusted with a flat-blade screwdriver. Brake adjusting spoons (**Figure 5-62**) and wire hooks designed for this specific purpose can make the job faster and easier, however.

Brake Cylinder Hones

Cylinder hones are used to clean light rust, corrosion, pits, and built-up residue from the bores of master cylinders, wheel cylinders, and calipers. A hone can be a very useful—sometimes necessary—tool when you have to overhaul a cylinder. A hone will not, however, save a cylinder with severe rust or corrosion.

Figure 5-62 A drum brake adjustment tool. *Reproduced under license from Snap-on Incorporated. All of the marks are marks of their owners.*

The most common cylinder hones have two or three replaceable abrasive stones at the ends of spring-loaded arms. Spring tension usually is adjustable to maintain proper stone pressure against the cylinder walls. The other end of the hone is mounted in a drill motor for use, and the hone's flexible shaft lets the motor turn the hone properly without being precisely aligned with the cylinder bore.

Another kind of hone is the **brush** or **ball hone**. It has abrasive balls attached to flexible metal brushes that are, in turn, mounted on the hone's flexible shaft. In use, centrifugal force moves the abrasive balls outward against the cylinder walls; tension adjustment is not required. A brush hone provides a superior surface finish and is less likely to remove too much metal than a stone hone.

Tubing Tools

The rigid brake lines, or pipes, of the hydraulic system are made of steel tubing to withstand high pressure and to resist damage from vibration, corrosion, and work hardening. Brake lines often can be purchased in preformed lengths to fit specific locations on specific vehicles. Straight brake lines can also be purchased in many lengths and several diameters and bent to fit specific vehicle locations. Even with prefabricated lines available, you probably will have many occasions to cut and bend steel lines and form flared ends for installation. The common tools (**Figure 5-63**) you should have are:

Figure 5-64 A digital caliper for measuring brake disc thickness. Courtesy of Honeywell International Inc.

- A tubing cutter and reamer
- Tube benders
- A double flaring tool for SAE flares
- An International Standards Organization (ISO) flaring tool for European-style ISO flares

Brake Disc Micrometer

A special micrometer should be used to check the thickness of a rotor accurately. A brake disc micrometer has pointed anvils that allow the tip to fit into grooves worn on the rotor. This type of micrometer is read in the same way as other micrometers but is made with a range from 0.300 to 1.300 inches. Digital calipers are also used to measure disc brake thickness (**Figure 5-64**).

Drum Micrometer

A drum micrometer is a single-purpose instrument used to measure the inside diameter of a brake drum. A drum micrometer has two movable arms on a shaft (**Figure 5-65**). One arm has a precision dial indicator; the other arm has an outside anvil that fits against the inside of the drum. In use, the arms are secured on the shaft by lock screws that fit into grooves every 1/8 inch (0.125) on the shaft. The dial indicator is graduated in 0.005-inch increments.

Metric drum micrometers work the same way except that the shaft is graduated in 1 cm major increments and the lock screws fit in notches every 2 mm.

Figure 5-63 A typical tubing tool set. Reproduced under license from Snap-on Incorporated. All of the marks are marks of their owners.

Figure 5-65 A drum micrometer.

Brake Shoe Adjusting Gauge (Calipers)

A brake shoe adjusting gauge is an inside-outside measuring device (**Figure 5-66**). This gauge is often called a brake shoe caliper. During drum brake service, the inside part of the gauge is placed inside a newly surfaced drum and expanded to fit the drum diameter. The lock screw is then tightened and the gauge moved to the brake shoes installed on the backing plate. The brake shoes are then adjusted until the outside part of the gauge just slips over them. This action provides a rough adjustment of the brake shoes. Final adjustment must still be done after the drum is installed, but the brake shoe gauge makes the job faster.

Figure 5-66 A drum brake shoe adjusting gauge.

Figure 5-67 A bench brake lathe.

Brake Lathes

Brake lathes are special power tools used only for brake service. They are used to turn and resurface brake rotors and drums. Turning involves cutting away very small amounts of metal to restore the surface of the rotor or drum. The traditional brake lathe is an assembly mounted on a stand or workbench. The bench lathe requires that the drum or rotor be removed from the vehicle and mounted on the lathe for service (**Figure 5-67**).

As the drum or rotor is turned on the lathe spindle, a carbide steel cutting bit is passed over the drum or rotor friction surface to remove a small amount of metal. The cutting bit is mounted rigidly on a lathe fixture for precise control as it passes across the friction surface.

An on-car lathe (**Figure 5-68**) is bolted to the vehicle suspension or mounted on a rigid stand to provide a stable mounting point for the cutting tool. The rotor may be turned by either the vehicle's engine or drive train (for a FWD vehicle) or by an electric motor and drive attachment on the lathe. As the rotor is turned, the lathe cutting tool is moved across both surfaces of the rotor to refinish it. An on-car lathe not only has the obvious advantage of speed, it also rotates the rotor on the vehicle wheel bearings and hub so that these sources of runout, or wobble, are compensated for during the refinishing operation.

Bleeder Screw Wrenches

Special bleeder screw wrenches often are used to open bleeder screws. Bleeder screw wrenches are small, 6-point box wrenches with strangely offset handles for access to bleeder screws in awkward

Figure 5-68 An on-vehicle disc brake lathe.
Courtesy of RTI Technologies, Inc.

locations. The 6-point box end grips the screw more securely than a 12-point box wrench can and avoids damage to the screw.

Bleeding Tools

Removing the air from the closed hydraulic brake system is very important. This is done by bleeding the system. Bleeding can be done manually, with a vacuum pump, or with a pressure bleeder. The latter two are preferred because they are quick and very efficient, and the technician can do without an assistant.

HEATING AND AIR-CONDITIONING TOOLS

The repair and diagnostic tools for the heating, ventilation, and air-conditioning (A/C) systems are discussed in the following paragraphs. This discussion does not cover all of the tools you may need; rather, these tools are the most commonly used by the service industry. Details of when and how to use these tools are covered in Section 9 of this book.

Manifold Gauge Set

A **manifold gauge set** (Figure 5-69) is used when discharging, charging, evacuating, and for diagnosing trouble in an A/C system. With the new legislation on handling refrigerants, all gauge sets are required to have a valve device to close off the end of the hose so that the fitting not in use is automatically shut.

The low-pressure gauge is graduated into pounds of pressure from 1 to 120 (with cushion to 250) in 1-pound graduations, and, in the opposite direction, in inches of vacuum from 0 to 30. This is the gauge that should always be used in checking pressure on the

Figure 5-69 A manifold gauge set.

low-pressure side of the system. The high-pressure gauge is graduated from 0 to 500 pounds pressure in 10-pound graduations. This gauge is used for checking pressure on the high-pressure side of the system.

The gauge manifold is designed to control refrigerant flow. When the manifold test set is connected into the system, pressure is registered on both gauges at all times.

Because R-134a is not interchangeable with R-12, separate sets of hoses, gauges, and other equipment are required to service vehicles. All equipment used to service R-134a and R-12 systems must meet SAE standard J1991. The service hoses on the manifold gauge set must have manual or automatic backflow valves at the service port connector ends to prevent the refrigerant from being released into the atmosphere during connection and disconnection. Manifold gauge sets for R-134a can be identified by labels on the gauges and/or have a light blue color on the face of the gauges.

For identification purposes, R-134a service hoses must have a black stripe along their length and be clearly labeled. The low-pressure hose is blue with a black stripe. The high-pressure hose is red with black stripe and the center service hose is yellow with a black stripe. Service hoses for one type of refrigerant will not easily connect into the wrong system, as the fittings for an R-134a system are different than those used in an R-12 system.

Service Port Adapter Set

To connect a manifold gauge set to an A/C system, adapters are sometimes needed (Figure 5-70). The high-side fitting on many vehicles with an R-12 system may require the use of a special adapter to connect the manifold gauge set to the service port. The service hoses of some manifold gauge sets are not

Figure 5-70 An A/C port adapter set. Courtesy of SPX Service Solutions

equipped with a Schrader valve-depressing pin. Therefore, when connecting this type hose to a Schrader valve, an adapter must be used. The manifold and gauge sets for R-12 and R-134a are not interchangeable; therefore, there are no suitable adapters for using R-12 gauges on an R-134a system or vice versa.

Electronic Leak Detector

An electronic leak detector (**Figure 5-71**) is safe and effective and can be used with all types of refrigerants. A hand-held battery-operated electronic leak detector contains a test probe that is moved about 1 inch per second in areas of suspected leaks. Since refrigerant is heavier than air, the probe should be positioned below the test point. An alarm or a buzzer on the detector indicates the presence of a leak. On some models, a light flashes when refrigerant is detected.

Fluorescent Leak Tracer

To find a refrigerant leak using the fluorescent tracer system, first introduce a fluorescent dye into the

Figure 5-71 An electronic leak detector. Courtesy of SPX Service Solutions

Figure 5-72 With a fluorescent tracer system, refrigerant leaks will glow brightly when inspected with a UV/Blue light as a luminous yellow-green. Courtesy of Tracer Products

air-conditioning system with a special infuser included with the detector equipment. Run the air conditioner for a few minutes, giving the tracer dye fluid time to circulate and penetrate. Wear the tracer protective goggles and scan the system with a black-light glow gun. Leaks in the system will shine under the black light as a luminous yellow-green (**Figure 5-72**).

Refrigerant Identifier

A refrigerant identifier (**Figure 5-73**) is used to identify the type of refrigerant present in a system. This test should be done before any service work. The tester is used to identify the purity and quality of the refrigerant sample taken from the system.

Refrigerant Recycling/Charging Stations

A charging station (**Figure 5-74**) removes, evacuates, and recharges an A/C system. The amount of

Figure 5-73 A refrigerant identifier (analyzer).

Figure 5-74 A dual (R-12 and R-134a) charging station. Courtesy of RTI Technologies, Inc.

refrigerant put into the system is adjusted through controls on the station.

Special equipment is used to remove and recycle the refrigerant in a system (**Figure 5-75**). These machines draw the old refrigerant out of the system,

Figure 5-75 A single-pass refrigerant recovery and recycling machine. Courtesy of RTI Technologies, Inc.

Figure 5-76 A dial-type thermometer used to check A/C operation. Courtesy of SPX Service Solutions

filter it, separate the oil, remove moisture and air, and store the refrigerant for future use.

All recycled refrigerant must be safely stored in DOT CFR Title 49 or UL-approved containers. Before recycled refrigerant can be used, it must be checked for noncondensable gases.

Thermometer

A digital readout or dial-type **thermometer** (**Figure 5-76**) is often used to measure the air temperature at the vent outlets, which indicates the overall performance of the system. The thermometer can also be used to check the temperature of refrigerant lines, hoses, and components while diagnosing a system. While doing the latter, an electronic pyrometer works best and is often used.

Compressor Tools

Although compressors are usually replaced when they are faulty, certain service procedures for them are standard practice. Most of these procedures focus on compressor clutch and shaft seal service and they require special tools. Clutch plate tools are required to gain access to the shaft seal. They are also needed to reinstall the clutch plate after service.

Many different tools are required to perform these services to a compressor. Typically to replace a shaft seal, you will need an adjustable or fixed spanner wrench, clutch plate installer/remover, ceramic seal installer/remover, seal assembly installer/remover, seal seat installer/remover, shaft seal protector, snapping pliers, O-ring remover, and O-ring installer. Some of these tools are for a specific model compressor; others are universal fit or have interchangeable parts to allow them to work on a variety of compressors.

Hose and Fitting Tools

An A/C system is a closed system, meaning outside air should never enter the system and the refrigerant in the system should never exit to the outside. To maintain this closed system, special fittings and hoses are used. Often, special tools, such as the spring-lock coupling tool set, are required when servicing the system's fittings and hoses. Without this tool, it is impossible to separate the connector and not damage it.

KEY TERMS

Ammeter	Ohmmeter
Ball hone	Pressure gauge
Boring bar	Pyrometer
Brush hone	Ridge reamer
Compression gauge	Ring compressor
Connector pick	Ring expander
Continuity tester	Ring groove cleaner
Cylinder hone	Scan tool
Cylinder leakage tester	Spark tester
Dial bore gauge	Stethoscope
Digital multimeter (DMM)	Tachometer
Dual-trace	Testlight
Dynamometer	Thermometer
Glaze breaker	Timing light
Hydrometer	Torque angle gauge
Inclinometer	Trace
Insulation resistance tester	Transient voltage
Lab scope	Vacuum
Lineman's gloves	Valve spring compressor
Logic probe	Valve spring tester
Manifold gauge set	VAT
Multimeter	Voltmeter
Noid light	Waveform

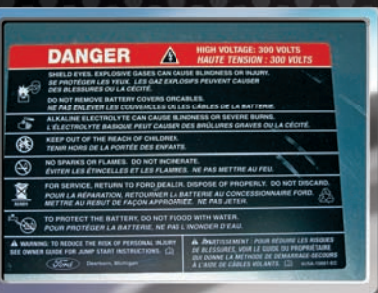

SUMMARY

- Common diagnostic tools used to check an engine and its related systems include a compression gauge, cylinder leakage tester, oil pressure gauge, stethoscope, dial bore indicator, valve spring tester, cooling system pressure tester, coolant hydrometer, engine analyzers, fuel pressure gauge, injector balance tester, injector circuit test light, vacuum gauge, vacuum pump, vacuum leak detector, spark tester, logic probes, pyrometers, and exhaust analyzers.
- Common tools used to service an engine and its related systems include transaxle removal and installation equipment, ridge reamer, ring compressor, ring expander, ring groove cleaner, cylinder deglazer, cylinder hone, boring bar, cam bearing driver set, V-blocks, valve and valve seat resurfacing equipment, valve guide repair tools, valve spring compressor, torque angle gauge, oil priming tool, a coolant recovery and recycle system, fuel injector cleaners, fuel line tools, pinch-off pliers, timing light, and spark plug sockets.
- Some of the common diagnostic tools for electronic and electrical systems include a testlight, continuity tester, voltmeter, ohmmeter, ammeter, volt/ampere tester, DMM, lab scope, scan tools, and battery hydrometer.
- Common electrical and electronic system service tools include a computer memory saver, wire and terminal repair tools, headlight aimers, static straps, and sensor tools.
- The tools required to work on hybrid vehicles are the same as those used on a conventional vehicle with the addition of tools designed for high voltages, such as linemen's gloves, CAT III test equipment, and insulation resistance testers.
- Diagnostic tools for a vehicle's drivetrain include a drive shaft angle gauge and hydraulic pressure gauge set.
- Tools required to service the drivetrain include transaxle removal and installation equipment, transmission/transaxle holding fixtures, transmission jack, axle pullers, special tool sets, clutch alignment tool, clutch pilot bearing/bushing puller/installer, and universal joint tools.
- The various diagnostic tools used on a vehicle's running gear include a tire tread depth gauge, power steering pressure gauge, wheel alignment equipment, brake disc micrometer, and drum micrometer.
- Some of the common tools used to service a vehicle's running gear include control arm bushing tools, tie-rod end and ball joint pullers, front bearing hub tool, pitman arm puller, tie-rod sleeve adjusting tool, steering column special tool set, shock absorber tools, spring/strut compressor tool, power steering pump pulley special tool set, brake pedal depressor, tire changer, wheel balancer, wheel weight pliers, brake cleaning equipment and containment systems, holddown spring and return spring tools, boot drivers and pliers, caliper piston removal tools, drum brake adjusting tools, brake cylinder hones, tubing tools, brake shoe adjusting gauge, brake lathes, bleeder screw wrenches, and pressure bleeders.
- Common tools used to check a vehicle's heating and air-conditioning system include a manifold gauge set, a service port adapter set, an electronic leak detector, a fluorescent leak tracer, and a thermometer.
- Tools used to service air-conditioning systems include a refrigerant identifier, refrigerant charging station, refrigerant recovery and recycling system, compressor tools, and hose and fitting tools.

REVIEW QUESTIONS

- What are the two types of testlights and how do they differ?
- True or False?* Knurling is used to repair worn valve guides by increasing the inside diameter of the guide.
- Name the two basic types of compression gauges.
- What tool is used to test engine manifold vacuum?
- Which of the following statements is *not* true?
 - Exhaust analyzers allow a technician to look at the effectiveness of a vehicle's emission control systems.
 - Most exhaust analyzers measure HC in parts per million or grams per mile.
 - CO is measured as a percent of the total exhaust.
 - Emission controls greatly alter O₂ and CO₂ emissions.
- Technician A says that a brake disc micrometer has pointed anvils. Technician B says that a brake drum micrometer is a large inside micrometer that is read like any other micrometer. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- Technician A says that a pyrometer measures temperature. Technician B says that a thermometer measures temperature. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- True or False?* A lab scope is a visual voltmeter that shows voltage over a period of time.
- When using a voltmeter, Technician A connects it across the circuit being tested. Technician B connects the red lead of the voltmeter to the more positive side of the circuit. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- Technician A uses a digital volt/ohmmeter to test voltage. Technician B uses the same tool to test resistance. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- Technician A says that a charging station removes old refrigerant and recharges an A/C system. Technician B says that a charging cylinder meters out the desired amount of refrigerant by weight. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- Which of the following statements about manifold gauge sets is *not* true?
 - An adapter is required for using R-12 gauges on an R-1134a system.
 - A manifold gauge set is used when discharging, charging, and evacuating and for diagnosing trouble in an A/C system.
 - The gauge manifold is designed to control refrigerant flow. When the manifold test set is connected into the system, pressure is registered on both gauges at all times.
 - R-134a service hoses have a black stripe along their length, the low-pressure hose is blue, and the high-pressure hose is red.
- True or False?* A brake shoe adjusting gauge is an inside-outside measuring device used to initially adjust the expanse of brake shoes before the brake drum is installed.
- When conducting an oil pressure test: Technician A says that lower than normal pressure can be caused by a burned intake valve. Technician B says that lower than normal oil pressure can be caused by excessive engine bearing clearances. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- Which of the following conditions can be revealed by fuel pressure readings?
 - faulty fuel pump
 - faulty fuel pressure regulator
 - restricted fuel delivery system
 - all of the above
- Technician A uses a high-impedance testlight on the high-voltage systems in hybrid vehicles. Technician B uses only CAT-III test instruments to check high-voltage systems. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- Technician A says that a sulfated and plugged fuel injector is caused by electrical problems. Technician B says that a sulfated and plugged fuel injector can be cleaned. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B

18. The tests conducted by a scan tool can also be done by some _____.
 - a. fuel injector pulse testers
 - b. exhaust analyzers
 - c. engine analyzers
 - d. digital volt/ohmmeters
19. When using a fuel injector pulse tester, Technician A says that little or no pressure drop indicates a plugged or defective injector. Technician B says that no pressure drop indicates an overly rich condition. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
20. It is much easier to test current using an ammeter equipped with a(n) _____.
 - a. continuity tester
 - b. carbon pile
 - c. inductive pickup
 - d. tachometer
21. While discussing a clutch alignment tool: Technician A says that the part of the tool that fits into the clutch plate must have a slightly larger OD than the bore in the disc. Technician B says that the OD of the tool that goes into the pilot must be slightly smaller than the ID of the pilot bushing. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
22. *True or False?* The angle of the drive shaft at the transmission should equal its angle at the drive axle.
23. Technician A says that ball joints may be pressed into the control arm. Technician B says that ball joints may be riveted to the control arm. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
24. Which of the following is *not* a suitable way to bleed a hydraulic brake system?
 - a. manual bleeding
 - b. bench bleeding
 - c. pressure bleeding
 - d. vacuum bleeding
25. Hydraulic pressure gauges are used to diagnose all of these, except:
 - a. power steering systems
 - b. automatic transmissions
 - c. hydraulic-boost brake systems
 - d. engine compression

WORKING SAFELY IN THE SHOP

OBJECTIVES

- Understand the importance of safety and accident prevention in an automotive shop.
- Explain the basic principles of personal safety, including protective eye wear, clothing, gloves, shoes, and hearing protection.
- Explain the procedures and precautions for safely using tools and equipment.
- Explain the precautions that need to be followed to safely raise a vehicle on a lift.
- Explain what should be done to maintain a safe working area in a shop.
- Describe the unique safety considerations that must be adhered to when working on hybrid vehicles.
- Describe the purpose of the laws concerning hazardous wastes and materials, including the Right-To-Know laws.
- Describe your rights, as an employee and/or student, to have a safe place to work.

Working on automobiles can be dangerous. It can also be fun and very rewarding. To keep the fun and rewards rolling in, you need to try to prevent accidents by working safely. In an automotive repair shop, there is great potential for serious accidents, simply because of the nature of the business and the equipment used. When there is carelessness, the automotive repair industry can be one of the most dangerous occupations.

However, the chances of you being injured while working on a car are close to nil if you learn to work safely and use common sense. Shop safety is the responsibility of everyone in the shop—you, your fellow students or employees, and your employer or instructor. Everyone must work together to protect the health and welfare of all who work in the shop.

Unless you want to get hurt or want your fellow students or employees to get hurt, you should strive to work safely. Shop accidents can cause serious injury, temporary or permanent disability, and death.

This chapter covers many guidelines concerning personal, work area, tool and equipment, and hazardous material safety. In addition to this chapter, special warnings are given throughout this book to alert you to situations where carelessness could result in personal injury. When working on cars, always follow the safety guidelines given in service manuals and other technical literature. They are there for your protection.

PERSONAL SAFETY

To protect yourself from injuries, you must take precautions. This includes wearing protective gear, dressing appropriately, working professionally, and correctly handling tools and equipment.

Eye Protection

Your eyes can become infected or permanently damaged by many things in a shop. Consider the following:

- Dirt and sharp bits of rust can easily fall into your eyes while you are working under a vehicle.
- Some procedures, such as grinding, release tiny particles of metal and dust, which are thrown off at very high speeds. These particles can easily get into your eyes, scratching or cutting them.
- Pressurized gases and liquids escaping a ruptured hose or loose hose fitting can spray into your eyes and cause blindness.

To be safe, you should wear suitable eye protection whenever you are working in the shop. In most shops, this is not an option—you must wear eye protection. There are many types of eye protection available (**Figure 6-1**).

Safety glasses have lenses made of safety glass. They also offer some sort of side protection. To help

Figure 6-1 Various types of eye protection: safety (splash) goggles, face shield, and safety glasses.

develop the habit of wearing safety glasses, make sure the glasses fit well and feel comfortable.

Regular prescription glasses do not offer sufficient protection and, therefore, should not be worn as a substitute for safety glasses. Prescription glasses can be made with polycarbonate lenses and can be worn as safety glass if they are rated ANSI Z87 and have side shields fixed to the frame.

Some procedures may require that you wear additional eye protection. For example, when you are working around air conditioning systems, you should wear splash goggles and, when cleaning parts with a pressurized spray, you should wear a face shield. The face shield will also protect the rest of your face.

Eye First Aid If chemicals such as battery acid, fuel, or solvents get into your eyes, flush them continuously with clean water. Have someone call a doctor and get medical help immediately.

Many shops have eye wash stations or safety showers (**Figure 6-2**) that should be used whenever you or someone else has been sprayed or splashed with a chemical.

Clothing

Clothing that hangs out freely, such as shirttails, can create a safety hazard and cause serious injury. Nothing you wear should be allowed to dangle in the engine compartment or around equipment. Shirts should be tucked in and buttoned and long sleeves buttoned or carefully rolled up. Your clothing should be well fitted and comfortable but made with strong material. Some technicians prefer to wear coveralls or shop coats to protect their personal clothing. Your work clothes should offer you some protection but should not restrict your movement.

Figure 6-2 A combination eye wash and safety shower. Courtesy of DuPont Performance Coatings

Keep your clothing clean. If you spill gasoline or oil on yourself, change that item of clothing immediately. Oil against your skin for a prolonged period can produce rashes or other allergic reactions. Gasoline can irritate cuts and sores.

Hair and Jewelry

Long hair and loose, hanging jewelry can create the same type of hazard as loose-fitting clothing. They can get caught in moving engine parts and machinery. If you have long hair, tie it back or tuck it under a cap.

Rings, necklaces, bracelets, and watches should not be worn while working. A ring can rip your finger off, a watch or bracelet can cut your wrist, and a necklace can choke you. This is especially true when working with or around electrical wires. The metals in most

jewelry conduct electricity very well and can easily cause a short, through you, if it touches a bare wire.

Shoes

You should also protect your feet. Tennis and jogging shoes provide little protection if something falls on your foot. Boots or shoes made of leather or a material that approaches the strength of leather, offer much better protection from falling objects. There are many designs of safety shoes and boots that also have steel plates built into the toe and shank to protect your feet. Many also have soles that are designed to resist slipping on wet surfaces. Foot injuries are not only quite painful but can also put you out of work for some time.

Gloves

Good hand protection is often overlooked. A scrape, cut, or burn can seriously impair your ability to work for many days. A well-fitted pair of heavy work gloves should be worn while grinding, welding, or when handling chemicals or high-temperature components. Polyurethane or vinyl gloves should be worn when handling strong and dangerous caustic chemicals (**Figure 6-3**). These chemicals can easily burn your skin.

Figure 6-3 Polyurethane or vinyl gloves should be worn when handling strong and dangerous caustic chemicals.

Figure 6-4 Many technicians wear thin, surgical-type latex or nitrile gloves whenever they are working on vehicles.

Many technicians wear thin, surgical-type latex (**Figure 6-4**) or nitrile gloves whenever they are working on vehicles. These offer little protection against cuts but do offer protection against disease and grease buildup under and around your fingernails. Latex gloves are more comfortable but weaken when they are exposed to gas, oil, and solvents. Nitrile gloves are not as comfortable but they are not affected by gas, oil, and solvents. Your choice of hand protection should be based on what you are doing.

Disease Prevention

When you are ill with something that may be contagious, see a doctor and do not go to work or school until the doctor says there is little chance of someone else contracting the illness from you. Doing this will protect others, and if others do this you will be protected.

You should also be concerned with and protect yourself and others from bloodborne pathogens. **Bloodborne pathogens** are pathogenic microorganisms that are present in human blood and can cause disease. These pathogens include, but are not limited to, staph infections caused by the bacteria *Staphylococcus aureus*, hepatitis B virus (HBV), and human immunodeficiency virus (HIV). For everyone's protection, any injury that causes bleeding should be dealt with as a threat to others. You should avoid contact with the blood of another. If you need to administer some form of first aid, make sure you wear hand protection before you do so. You should also wear gloves and other protection when handling the item that caused the cut. This item should be sterilized immediately. Most importantly, like all injuries, report the accident to your instructor or supervisor.

Figure 6-5 While working in a noisy environment, your ears can be protected with earmuffs or earplugs.

Ear Protection

Exposure to very loud noise levels for extended periods can lead to hearing loss. Air wrenches, engines running under a load, and vehicles running in enclosed areas can all generate harmful levels of noise. Simple earplugs or earphone-type protectors (**Figure 6-5**) should be worn in environments that are constantly noisy.

Respiratory Protection

Technicians often work with chemicals that have toxic fumes. Air or respiratory masks should be worn whenever you will be exposed to toxic fumes. Cleaning parts with solvents and painting are the most common times when respiratory masks should be worn.

Masks should also be worn when handling parts that contain asbestos or when handling hazardous materials. The proper handling of these materials is covered in great detail later in this chapter.

Lifting and Carrying

At least once a week a technician will need to move something that is heavy. Knowing how to lift these heavy things can save your career. When lifting any object, follow these steps:

1. Place your feet close to the object. Position your feet so you will be able to maintain a good balance.
2. Keep your back and elbows as straight as possible. Bend your knees until your hands reach the best place to get a strong grip on the object (**Figure 6-6**).
3. If the part is in a cardboard box, make sure the box is in good condition. Old, damp, or poorly sealed boxes will tear and the part will fall out.

Figure 6-6 Use your leg muscles—never your back—to lift heavy objects.

4. Firmly grasp the object or container. Never try to change your grip as you move the load.
5. Keep the object close to your body, and lift it up by straightening your legs. Use your leg muscles, not your back muscles.
6. If you must change your direction of travel, never twist your body. Turn your whole body, including your feet.
7. When placing the object on a shelf or counter, do not bend forward. Place the edge of the load on the shelf and slide it forward. Be careful not to pinch your fingers.
8. When setting down a load, bend your knees and keep your back straight. Never bend forward. This strains the back muscles.
9. When lowering something heavy to the floor, set the object on blocks of wood to protect your fingers.

You should also use back-protection devices when you lift heavy objects. Always lift and work within your ability and ask others (or use a hoist) to help when you are not sure whether you can handle the size or weight of an object. Even small, compact parts can be surprisingly heavy or unbalanced. Think about how you are going to lift something before beginning.

CAUTION!

Trying to “muscle” something with your arms or back can result in severe damage to your back and may end your career and limit what you do the rest of your life!

Professional Behavior

Accidents can be prevented simply by the way you behave. The following list does not include everything you should or should not do; it merely gives some things to think about:

- Never smoke while working on a vehicle or while working with any machine in the shop.
- Playing around or “horseplay” is not fun when it sends someone to the hospital.
- To prevent serious burns, keep your skin away from hot metal parts such as the radiator, exhaust manifold, tailpipe, catalytic converter, and muffler.
- Always disconnect electric engine cooling fans when working around the radiator. Many of these will turn on without warning and can easily chop off a finger or hand. Make sure you reconnect the fan after you have completed your repairs.
- When working with a hydraulic press, make sure the pressure is applied in a safe manner. It is generally wise to stand to the side when operating the press.
- Properly store all parts and tools by putting them away in a place where people will not trip over them. This practice not only cuts down on injuries, it also reduces time wasted looking for a misplaced part or tool.
- Keep your work area clean and uncluttered. Make sure you clean up all spills before continuing to work.

TOOL AND EQUIPMENT SAFETY

An automotive technician must adhere to the following shop safety guidelines when using all tools and equipment.

Hand Tool Safety

Careless use of simple hand tools such as wrenches, screwdrivers, and hammers causes many shop accidents that could be prevented. Keep in mind the following tips when using hand tools:

- Keep all hand tools grease-free. Oily tools can slip out of your hand, causing broken fingers or at least cut or skinned knuckles.
- Inspect your tools for cracks, broken parts, or other dangerous conditions before you use them.
- Hand tools should only be used for the purpose they were designed for. Use the right tool for the job.
- Make sure the tool is of professional quality.
- Never use broken or damaged tools.

- When using a wrench, always pull it, not push it, toward you.
- Always use the correct size of wrench.
- Use a box-end or socket wrench whenever possible.
- Do not use deep-well sockets when a regular size socket will work. The longer socket develops more twist torque and tends to slip off the fastener.
- Use an adjustable wrench only when it is absolutely necessary; pull the wrench so that the force of the pull is on the nonadjustable jaw.
- When using an air impact wrench, always use impact sockets.
- Never use wrenches or sockets that have cracks or breaks.
- Never use a wrench or pliers as a hammer.
- Never use pliers to loosen or tighten a nut; use the correct wrench.
- Always be sure to strike an object with the full face of the hammerhead.
- Always wear safety glasses when using a hammer and/or chisel.
- Never strike two hammer heads together.
- Never use screwdrivers as chisels.
- Be careful when using sharp or pointed tools.
- Do not place sharp tools or other sharp objects into your pockets.
- If a tool is supposed to be sharp, make sure it is sharp. Dull tools can be more dangerous than sharp tools.
- Use knives, chisels, and scrapers in a motion that will keep the point or blade moving away from your body.
- Always hand a pointed or sharp tool to someone else with the handle toward the person to whom you are handing the tool.

Power Tool Safety

CAUTION!

Carelessness or mishandling of power tools can cause serious injury. Make sure you know how to operate a tool before using it.

Power tools are operated by an outside power source, such as electricity, compressed air, or hydraulic pressure. Always respect the tool and its power source. Carelessness can result in serious injury. Also, always

wear safety glasses when using power tools. Never try to use a tool beyond its stated capacity.

Electrical Tools When using an electrically powered tool, make sure it is properly grounded. Check the wiring for insulation cracks, as well as bare wires, before using it. Also, when using electrical power tools, never stand on a wet or damp floor. Before plugging in any electric tool, make sure its switch is in the *off* position. When you are finished using the tool, turn it off and unplug it. Never leave a running power tool unattended.

When using power equipment on a small part, never hold the part in your hand. Always mount the part in a bench vise or use vise grip pliers.

When using a bench or floor grinding wheel, check the machine and the grinding wheels for signs of damage before using them. If the wheels are damaged, they should be replaced before using the machine. Make sure the speed rating of the replacement wheels match the speed of the machine. Be sure to place all safety guards in position (**Figure 6-7**). A safety guard is a protective cover over a moving part. Although the safety guards are designed to prevent injury, you should still wear safety glasses and/or a face shield while using the machine. Make sure there are no people or parts around the machine before starting it. Keep your hands and clothing away from the moving parts. Maintain a balanced stance while using the machine.

Compressed Air Tools Tools that use compressed air are called **pneumatic tools**. Compressed air is used to inflate tires, apply paint, and drive tools, such as air ratchets and impact wrenches. Pneumatic tools must always be operated at the pressure recommended by the manufacturer. Before using a pneumatic tool,

check all hose connections for leaks. Also check for air line damage.

When using an air nozzle, wear safety glasses and/or a face shield. Particles of dirt and pieces of metal, blown by the high-pressure air, can penetrate your skin or get into your eyes. Always hold an air nozzle or air control device securely when starting or shutting off the compressed air. A loose nozzle can whip suddenly and cause serious injury. Never point an air nozzle at anyone. Never use compressed air to blow dirt from your clothes or hair. Never use compressed air to clean the floor or workbench. Never spin bearings with compressed air. If the bearing is damaged, one of the steel balls or rollers might fly out and cause serious injury.

Lift Safety

Always be careful when raising a vehicle on a lift or a hoist. Adapters and hoist plates must be positioned correctly on twin post- and rail-type lifts to prevent damage to the underbody of the vehicle. There are specific lift points. These points allow the weight of the vehicle to be evenly supported by the adapters or hoist plates. The correct lift points can be found in the vehicle's service manual. **Figure 6-8** shows typical locations for unibody and frame cars. These diagrams are for illustration only. Always follow the manufacturer's instructions. Before operating any lift or hoist, you should already have been trained on the proper use of the lift. Always follow

Figure 6-7 A bench grinder with its safety shields in place.

Figure 6-8 Typical lifting points: The correct ones for a vehicle are given in the service manual for that vehicle.

the recommended instructions for operating a particular lift.

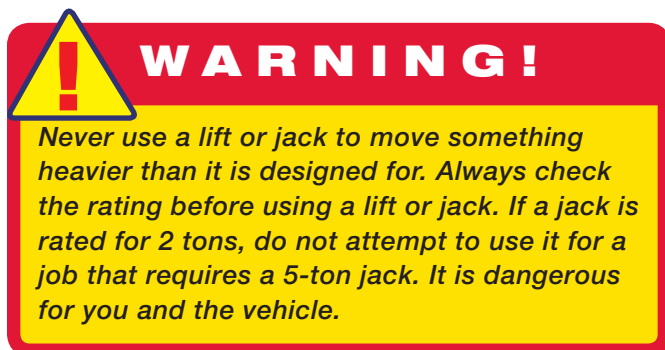

Once you feel the lift supports are properly positioned under the vehicle, raise the lift until the supports contact the vehicle. Then, check the supports to make sure they are in full contact with the vehicle. Shake the vehicle to make sure it is securely balanced on the lift, then raise the lift to the desired working height.

The Automotive Lift Institute (ALI) is an association concerned with the design, construction, installation, operation, maintenance, and repair of automotive lifts. Their primary concern is safety. Every lift approved by ALI has the label shown in **Figure 6-9**. It is a good idea to read through the safety tips included on that label before using a lift.

Jack and Jack Stand Safety

A vehicle can be raised off the ground by a hydraulic jack (**Figure 6-10**). A handle on the jack is moved up and down to raise part of a vehicle and a valve is turned to release the hydraulic pressure in the jack to lower the part. At the end of the jack is a lifting pad. The pad must be positioned under an area of the vehicle's frame or at one of the manufacturer's recommended lift points. Never place the pad under the floorpan or under steering and suspension components, because they can easily be damaged by the weight of the vehicle. Always position the jack so that the wheels of the vehicle can roll as the vehicle is being raised.

Safety stands, also called **jack stands** (**Figure 6-11**), are supports of various heights that sit on the floor. They are placed under a sturdy chassis member, such

AUTOMOTIVE LIFT SAFETY TIPS

Post these safety tips where they will be a constant reminder to your lift operator. For information specific to the lift, always refer to the lift manufacturer's manual.

1. Inspect your lift daily. Never operate if it malfunctions or if it has broken or damaged parts. Repairs should be made with original equipment parts.
2. Operating controls are designed to close when released. Do not block open or override them.
3. Never overload your lift. Manufacturer's rated capacity is shown on nameplate affixed to the lift.
4. Positioning of vehicle and operation of the lift should be done only by trained and authorized personnel.
5. Never raise vehicle with anyone inside it. Customers or by-standers should not be in the lift area during operation.
6. Always keep lift area free of obstructions, grease, oil, trash, and other debris.
7. Before driving vehicle over lift, position arms and supports to provide unobstructed clearance. Do not hit or run over lift arms, adapters, or axle supports. This could damage lift or vehicle.
8. Load vehicle on lift carefully. Position lift supports to contact at the vehicle manufacturer's recommended lifting points. Raise lift until supports contact vehicle. Check supports for secure contact with vehicle. Raise lift to desired working height. CAUTION: If you are working under vehicle, lift should be raised high enough for locking device to be engaged.
9. Note that with some vehicles, the removal (or installation) of components may cause a critical shift in the center of gravity and result in raised vehicle instability. Refer to the vehicle manufacturer's service manual for recommended procedures when vehicle components are removed.
10. Before lowering lift, be sure tool trays, stands, etc. are removed from under vehicle. Release locking devices before attempting to lower lift.
11. Before removing vehicle from lift area, position lift arms and supports to provide an unobstructed exit (See item #7).

These "Safety Tips," along with "Lifting it Right," a general lift safety manual, are presented as an industry service by the Automotive Lift Institute. For more information on this material, write to: ALI, P.O. Box 1519, New York, NY 10101.

Look For This Label on all Automotive Service Lifts.

Figure 6-9 Automotive lift safety tips. Courtesy of the Automotive Lift Institute

as the frame or axle housing, to support the vehicle. Once the safety stands are in position, the hydraulic pressure in the jack should be slowly released until the weight of the vehicle is on the stands. Like jacks, jack stands also have a capacity rating. Always use a jack stand of the correct rating.

Never move under a vehicle when it is supported by only a hydraulic jack. Rest the vehicle on the safety stands before moving under the vehicle.

The jack should be removed after the jack stands are set in place. This eliminates a hazard, such as a jack handle sticking out into a walkway. A jack handle that is bumped or kicked can cause a tripping accident or cause the vehicle to fall.

Figure 6-10 Typical hydraulic jack. Courtesy of Lincoln Automotive Company

Figure 6-12 A heavy-duty engine hoist. Courtesy of Lincoln Automotive Company

Figure 6-11 Jack stands should be used to support the vehicle after it has been raised by a jack.

Chain Hoist and Crane Safety

Heavy parts of the automobile, such as engines, are removed by using chain hoists (**Figure 6-12**) or cranes. Another term for a chain hoist is chain fall. Cranes often are called cherry pickers.

To prevent serious injury, chain hoists and cranes must be properly attached to the parts being lifted. Always use bolts with enough strength to support the object being lifted. After you have attached the lifting chain or cable to the part that is being removed, have your instructor check it. Place the chain hoist or crane directly over the assembly. Then, attach the lifting chain or cable to the hoist.

Figure 6-13 A solvent-based parts washer.

Cleaning Equipment Safety

Parts cleaning is a necessary step in most repair procedures. Cleaning automotive parts can be divided into three basic categories.

Chemical cleaning relies primarily on some type of chemical action to remove dirt, grease, scale, paint, or rust (**Figure 6-13**). A combination of heat, agitation, mechanical scrubbing, or washing may be used to help remove dirt. Chemical cleaning equipment

includes small parts washers, hot/cold tanks, pressure washers, spray washers, and salt baths.

Thermal cleaning relies on heat, which bakes off or oxidizes the dirt. Thermal cleaning leaves an ash residue on the surface that must be removed by an additional cleaning process, such as airless shot blasting or spray washing.

Abrasive cleaning relies on physical abrasion to clean the surface. This includes everything from a wire brush to glass bead blasting, airless steel shot blasting, abrasive tumbling, and vibratory cleaning. Chemical in-tank solution sonic cleaning might also be included here because it relies on the scrubbing action of ultrasonic sound waves to loosen surface contaminants.

Vehicle Operation

When a customer brings a vehicle in for service, certain driving rules should be followed to ensure your safety and the safety of those working around you. For example, before moving a car into the shop, buckle your seat belt. Make sure no one is near, the way is clear, and there are no tools or parts under the car before you start the engine.

Check the brakes before putting the vehicle in gear. Then, drive slowly and carefully in and around the shop.

When road testing the car, obey all traffic laws. Drive only as far as is necessary to check the automobile and verify the customer's complaint. Never make excessively quick starts, turn corners too quickly, or drive faster than conditions allow.

If the engine must be kept running while you are working on the car, block the wheels to prevent the vehicle from moving. Place the transmission in park for automatic transmissions or in neutral for manual transmissions. Set the parking (emergency) brake. Never stand directly in front of or behind a running vehicle.

When parking a vehicle in the shop, always roll the windows down. This allows for access if the doors accidentally lock.

Venting the Engine's Exhaust Whenever you need to have the engine running for diagnosis or service, the engine's exhaust must be vented to the outside. Carbon monoxide (CO) is present in the exhaust. CO is an odorless, tasteless, and colorless deadly gas. Inhaling CO can cause brain damage and, in severe cases, death. Early symptoms of CO poisoning include headaches, nausea, and fatigue.

Most shops have an exhaust ventilation system (Figure 6-14); always use it. These systems collect the engine's exhaust and release it to the outside air.

Figure 6-14 When running an engine in a shop; make sure the vehicle's exhaust is connected to the shop's exhaust ventilation system.

Before running an engine in the shop, connect a hose from the vehicle's tailpipe to the intake for the vent system. Make sure the vent system is turned on before running the engine. If the work area does not have an exhaust venting system, use a hose to direct the exhaust out of the building.

Electrical Safety

Much of your work on an automobile will be around or with the vehicle's electrical system. To prevent personal injury or damage to the vehicle, you should always take the necessary precautions before working. When possible, you should disconnect the vehicle's battery before disconnecting any electrical wire or component. This prevents the possibility of a fire or electrical shock. It also eliminates the possibility of an accidental short, which can ruin the car's electrical system. Disconnect the negative or ground cable first (Figure 6-15), then disconnect the positive cable.

Figure 6-15 Before doing any electrical work or working around the battery, disconnect the negative lead of the battery.

Because electrical circuits require a ground to be complete, by removing the ground cable you eliminate the possibility of a circuit accidentally becoming completed. When reconnecting the battery, connect the positive cable first, then the negative.

Also, remove wristwatches and rings before servicing any part of the electrical system. This helps prevent the possibility of electrical arcing and burns. When disconnecting electrical connectors, do not pull on the wires. When reconnecting the connectors, make sure they are securely connected.

Battery Precautions Because the vehicle's electrical power is stored in a battery or battery pack, special handling precautions must be followed when working with or near batteries. Hybrid and other electric vehicles have very high voltages; therefore, special precautions apply to these vehicles and are given following the general precautions for batteries.

- Make sure you are wearing safety glasses (preferably a face shield) and protective clothing when working around and with batteries.
- Keep all flames, sparks, and excessive heat away from the battery at all times, especially when it is being charged.
- Never smoke near the top of a battery and never use a lighter or match as a flashlight.
- Never lay metal tools or other objects on the battery because a short circuit across the terminals can result.
- All batteries have an electrolyte, which is very corrosive. It can cause severe injuries if it comes in contact with your skin or eye. If electrolyte gets on you, immediately wash with baking soda and water. If the acid gets in your eyes, immediately flush them with cool water for a minimum of 15 minutes and get immediate medical attention.
- Lead-acid batteries use sulfuric acid as the electrolyte. Sulfuric acid is poisonous, is highly corrosive, and produces gases that can explode in high heat.
- Acid from the battery damages a vehicle's paint and metal surfaces and harms shop equipment. Neutralize any electrolyte spills during servicing.
- The most dangerous battery is one that has been overcharged. It is hot and has been, or still may be, producing large amounts of hydrogen. Allow the battery to cool before working with or around it. Also never use or charge a battery that has frozen electrolyte.
- Always use a battery carrier or lifting strap to make moving and handling batteries easier and safer.
- Always charge a battery in well-ventilated areas.
- Never connect or disconnect charger leads when the charger is turned on. This generates a dangerous spark.
- Never recharge the battery when the system is on.
- Turn off all accessories before charging the battery and correct any parasitic drain problems.
- Make sure the charger's power switch is off when you are connecting or disconnecting the charger cables to the battery.
- Always double-check the polarity of the battery charger's connections before turning the charger on. Incorrect polarity can damage the battery or cause it to explode.
- Never attempt to use a charger as a boost to start the engine.

High-Voltage Systems Electric drive vehicles (battery-operated, hybrid, and fuel cell electric vehicles) have high-voltage electrical systems (from 42 volts to 650 volts). These high voltages can kill you! Fortunately, most high-voltage circuits are identifiable by size and color. The cables have thicker insulation and are typically colored orange (**Figure 6-16**). The connectors are also colored orange. On some vehicles, the high-voltage cables are enclosed in an orange shielding or casing; again the orange indicates high voltage. In addition, the high-voltage battery pack and most high-voltage components have "High Voltage" caution labels (**Figure 6-17**). Be careful not to touch these wires and parts. There are other safety precautions that should always be adhered to when working on an electric drive vehicle:

Figure 6-16 The high-voltage cables on this Civic hybrid are colored orange and are enclosed in orange casing.

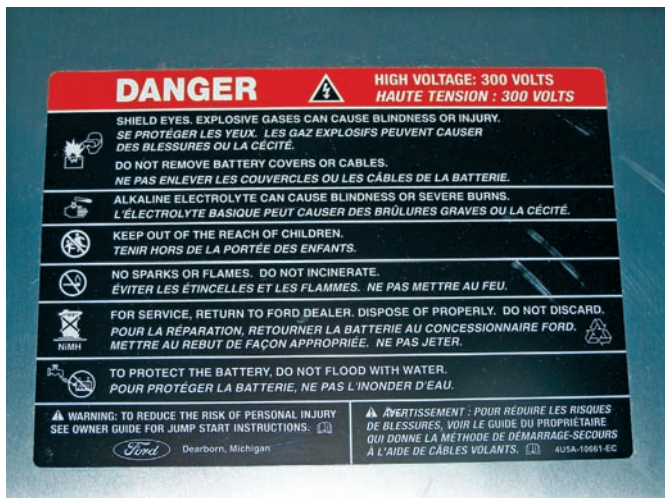

Figure 6-17 Most high-voltage components in a hybrid vehicle have “High Voltage” caution labels.

- Always adhere to the safety guidelines given by the vehicle’s manufacturer.
- Obtain the necessary training before working on these vehicles.
- Be sure to perform each repair operation correctly.
- Disable or disconnect the high-voltage system before performing services to those systems. Do this according to the procedures given by the manufacturer.
- Any time the engine is running in a hybrid vehicle, the generator is producing high-voltage. Take care to prevent being shocked.
- Before doing any service to an electric drive vehicle, make sure the power to the electric motor is disconnected or disabled.
- Systems may have a high-voltage capacitor that must be discharged after the high-voltage system has been isolated. Make sure to wait the prescribed amount of time (normally about 10 minutes) before working on or around the high-voltage system.
- After removing a high-voltage cable, cover the terminal with vinyl electrical tape.
- Always use insulated tools.
- Use only the tools and test equipment specified by the manufacturer and follow the test procedures defined by the equipment manufacturer.
- Alert other technicians that you are working on the high-voltage systems with a warning sign such as “High-voltage work: Do not touch.”
- Always follow the instructions given by the manufacturer for removing high-voltage battery packs.
- Wear insulating gloves, commonly called “line-man’s gloves,” when working on or around the

high-voltage system. Make sure they have no tears, holes, or cracks and that they are dry. The integrity of the gloves should be checked before using them.

- Always install the correct type of circuit protection device into a high-voltage circuit.
- Many electric motors have a strong permanent magnet in them; do not handle these parts if you have a pacemaker.
- When an electric drive vehicle needs to be towed into the shop for repairs, make sure it is not towed on its drive wheels. Doing this will drive the generator(s), which can overcharge the batteries and cause them to explode. Always tow these vehicles with the drive wheels off the ground or move them on a flat bed.

Rotating Pulleys and Belts

Be very careful around belts, pulleys, wheels, chains, or any other rotating mechanism. When working around an engine’s drive belts and pulleys, make sure your hands, shop towels, or loose clothing do not come in contact with the moving parts. Hands and fingers can be quickly pulled into a revolving belt or pulley even at engine idle speeds.

WARNING!

Be careful when working around electric engine cooling fans. These fans are controlled by a thermostat and can come on without warning, even when the engine is not running. Whenever you must work around these fans, disconnect the electrical connector to the fan motor before reaching into the area around the fan.

WORK AREA SAFETY

The floor of your work area and bench tops should be kept clean, dry, and orderly. Any oil, coolant, or grease on the floor can make it slippery. Slips can result in serious injuries. To clean up oil, use commercial oil absorbent. Also, keep all water off the floor. Water is slippery on smooth floors, and electricity flows well through water. Aisles and walkways should be kept clean and wide enough to easily move through. Make sure the work areas around machines are large enough to safely operate the machine.

Make sure all drain covers are snugly in place. Open drains or covers that are not flush to the floor can cause toe, ankle, and leg injuries.

Keep an up-to-date list of emergency telephone numbers clearly posted next to the telephone. These numbers should include a doctor, hospital, and fire and police departments. Also, the work area should have a first-aid kit for treating minor injuries and eye-flushing kits readily available. You should know where these items are kept.

Fire Hazards and Prevention

Gasoline is a highly flammable volatile liquid. Something that is flammable catches fire and burns easily. A volatile liquid is one that vaporizes very quickly. Flammable volatile liquids are potential fire bombs. Always keep gasoline, ethanol, or diesel fuel in an approved safety can (**Figure 6-18**), and never use gasoline to clean your hands or tools.

The presence of gasoline is so common that its dangers are often forgotten. A slight spark or an increase in heat can cause a fire or explosion. Gasoline fumes are heavier than air. Therefore, when an open container of gasoline is sitting about, the fumes spill out over the sides of the container. These fumes are more flammable than liquid gasoline and can easily explode.

CAUTION!

Never siphon gasoline or diesel fuel with your mouth. These liquids are poisonous and can make you sick or fatally ill.

Never smoke around gasoline or in a shop filled with gasoline fumes. If the vehicle has a gasoline leak or you have caused a leak by disconnecting a fuel line, wipe it up immediately and stop the leak. Make sure that any grinding or welding that may be taking place in the area is stopped until the spill is totally cleaned up and the floor has been flushed with water. The rags used to wipe up the gasoline should be taken outside to dry, then stored in an approved dirty rag container. If vapors are present in the shop, have the doors open and turn on the ventilating system. It takes only a small amount of fuel mixed with air to cause combustion.

Ethanol Most commonly found as E85 (15% gasoline mixed with 85% ethanol), ethanol is a very volatile liquid. Ethanol is a non-petroleum-based fuel and is used as an alternative fuel to gasoline. Ethanol is also used as an additive to increase the octane rating of gasoline. Handle and store E85 in the same way as gasoline.

Diesel Fuel Diesel fuel is not as volatile as gasoline but should be stored and handled in the same way.

Figure 6-18 Flammable liquids should be stored in safety-approved containers.

It is also not as refined as gasoline and tends to be a very dirty fuel. It normally contains many impurities, including active microscopic organisms that can be highly infectious. If diesel fuel happens to get on an open cut or sore, thoroughly wash it immediately.

Solvents Cleaning solvents are also not as volatile as gasoline, but they are still flammable. These should be stored and treated in the same way as gasoline. Handle all solvents (or any liquids) with care to avoid spillage. Keep all solvent containers closed, except when pouring. Proper ventilation is very important in areas where volatile solvents and chemicals are used. Solvent and other combustible materials must be stored in approved and designated storage cabinets or rooms (**Figure 6-19**). Storage rooms should have adequate ventilation.

Discard or clean all empty solvent containers. Solvent fumes in the bottom of these containers are very flammable. Never light matches or smoke near flammable solvents and chemicals, including battery acids.

Rags Oily or greasy rags can also be a source for fires. These rags should be stored in an approved container (**Figure 6-20**) and never thrown out with normal trash. When these oily, greasy, or paint-soaked rags are left lying about or are not stored properly, they

Figure 6-19 Store combustible materials in approved safety cabinets.

Figure 6-20 Dirty rags and towels should be kept in an approved container. *Courtesy of the DuPont Company*

Figure 6-21 Know the location and types of fire extinguishers that are available in the shop.

can cause spontaneous combustion. Spontaneous combustion results in a fire that starts by itself, that is, without a match.

Fire Extinguishers

You should know the location of all fire extinguishers (**Figure 6-21**) and fire alarms in the shop and you should also know how to use them before you need one. You should also be aware of the different types of fires and fire extinguishers (**Table 6-1**). All extinguishers are marked with a symbol or letter signifying the class of fire for which they are intended. Using the wrong type of extinguisher may cause the fire to grow instead of being put out.

If a fire extinguisher is not handy, a blanket or fender cover may be used to smother the flames. Be careful when doing this because the heat of the fire may burn you and the blanket. If the fire is too great to smother, move everyone away from the fire and call the local fire department. A simple under-the-hood fire can cause the total destruction of the car and the building and can take some lives. You must be able to respond quickly and precisely to avoid a disaster.

Using a Fire Extinguisher Remember, never open doors or windows during a fire unless it is absolutely necessary; the extra draft will only make the fire worse. Make sure the fire department is contacted before or during your attempt to extinguish a fire. To extinguish a fire, stand 6 to 10 feet from the fire. Before releasing the agent from the extinguisher, hold the extinguisher firmly in an upright position. Aim the nozzle at the base and use a side-to-side motion, sweeping the

TABLE 6-1 GUIDE TO EXTINGUISHER SELECTION

	Class of Fire	Typical Fuel Involved	Type of Extinguisher
Class A Fires  (green)	For Ordinary Combustibles Put out a class A fire by lowering its temperature or by coating the burning combustibles.	Wood Paper Cloth Rubber Plastics Rubbish Upholstery	Water* ¹ Foam* Multipurpose dry chemical ⁴
Class B Fires  (red)	For Flammable Liquids Put out a class B fire by smothering it. Use an extinguisher that gives a blanketing, flame-interrupting effect; cover whole flaming liquid surface.	Gasoline Oil Grease Paint Lighter fluid	Foam* Carbon dioxide ⁵ Halogenated agent ⁶ Standard dry chemical ² Purple K dry chemical ³ Multipurpose dry chemical ⁴
Class C Fires  (blue)	For Electrical Equipment Put out a class C fire by shutting off power as quickly as possible and by always using a nonconducting extinguishing agent to prevent electric shock.	Motors Appliances Wiring Fuse boxes Switchboards	Carbon dioxide ⁵ Halogenated agent ⁶ Standard dry chemical ² Purple K dry chemical ³ Multipurpose dry chemical ⁴
Class D Fires  (yellow)	For Combustible Metals Put out a class D fire of metal chips, turnings, or shavings by smothering or coating with a specially designed extinguishing agent.	Aluminum Magnesium Potassium Sodium Titanium Zirconium	Dry powder extinguishers and agents only

*Cartridge-operated water, foam, and soda-acid types of extinguishers are no longer manufactured. These extinguishers should be removed from service when they become due for their next hydrostatic pressure test.

Notes:

- (1) Freezes in low temperatures unless treated with antifreeze solution, usually weighs more than 20 pounds (9 kg), and is heavier than any other extinguisher mentioned.
- (2) Also called ordinary or regular dry chemical (sodium bicarbonate).
- (3) Has the greatest initial fire-stopping power of the extinguishers mentioned for class B fires. Be sure to clean residue immediately after using the extinguisher so sprayed surfaces will not be damaged (potassium bicarbonate).
- (4) The only extinguishers that fight A, B, and C classes of fires. However, they should not be used on fires in liquefied fat or oil of appreciable depth. Be sure to clean residue immediately after using the extinguisher so sprayed surfaces will not be damaged (ammonium phosphates).
- (5) Use with caution in unventilated, confined spaces.
- (6) May cause injury to the operator if the extinguishing agent (a gas) or the gases produced when the agent is applied to a fire is inhaled.

entire width of the fire (**Figure 6-22**). Stay low to avoid inhaling the smoke. If it gets too hot or too smoky, get out. Remember, never go back into a burning building for anything. To help remember how to use an extinguisher, remember the word “PASS.”

Pull the pin from the handle of the extinguisher.
Aim the extinguisher’s nozzle at the base of the fire.
Squeeze the handle.
Sweep the entire width of the fire with the contents of the extinguisher.

Figure 6-22 Aim the nozzle at the base of the fire and sweep the entire width of the fire.

MANUFACTURERS' WARNINGS AND GOVERNMENT REGULATIONS

A typical shop contains many potential health hazards for those working in it. These hazards can cause injury, sickness, health impairments, discomfort, and even death. These hazards can be classified as:

Chemical hazards—caused by high concentrations of vapors, gases, or dust

Hazardous wastes—those substances that are the result of a service

Physical hazards—include excessive noise, vibration, pressures, and temperatures

Ergonomic hazards—conditions that impede normal body position and motion

Many government agencies have the responsibility to ensure safe work environments for all workers. Federal agencies include the **Occupational Safety and Health Administration (OSHA)**, Mine Safety and Health Administration (MSHA), and National Institute for Occupational Safety and Health (NIOSH). These agencies, as well as state and local governments, have instituted regulations that must be understood and followed. Everyone in a shop has the responsibility to adhere to these regulations.

OSHA

In 1970, OSHA was formed to “assure safe and healthful working conditions for working men and women; by authorizing enforcement of the standards developed under the Act; by assisting and encouraging the States in their efforts to assure safe and healthful working conditions by providing

research, information, education, and training in the field of occupational safety and health.”

The established safety standards are consistent across the country. It is the employer’s responsibility to provide a place of employment free from all recognized hazards. All automotive industry safety and health issues are controlled by OSHA.

RIGHT-TO-KNOW LAW

OSHA also regulates the use of many potentially hazardous materials. The **Environmental Protection Agency (EPA)** regulates their disposal.

Servicing and maintaining a vehicle involves the handling and managing of a wide variety of materials and wastes. Some of these wastes can be toxic to fish, wildlife, and humans when improperly managed. It is to the shop’s legal and financial advantage to manage the wastes properly and, even more importantly, to prevent the pollution of our natural resources.

An important part of a safe work environment is the employee’s knowledge of potential hazards. All employees in a shop are protected by **Right-To-Know Laws** concerning all potentially hazardous materials. OSHA’s Hazard Communication Standard was originally intended for chemical companies and manufacturers that require employees to handle potentially hazardous materials. Since then federal courts decided that these regulations should apply to all companies, including auto repair shops.

The general intent of Right-To-Know Laws is for employers to provide their employees with a safe working place. All employees must be trained about their rights under the legislation, the nature of the hazardous chemicals in their workplace, and the contents of the labels on the chemicals. All of the information about each chemical must be posted on **material safety data sheets (MSDS)** and must be accessible. The manufacturer of the chemical must provide these sheets upon request (**Figure 6-23**). They detail the chemical composition and precautionary information for all products that can present a health or safety hazard.

An MSDS lists the product’s ingredients, potential health hazards, physical description, explosion and fire data, reactivity and stability data, and protection data including first aid and proper handling.

All hazardous materials must be properly labeled, indicating what health, fire, or reactivity hazard they pose and what protective equipment is necessary when handling each. The manufacturer of the hazardous materials must provide all warnings and

Figure 6-23 Material safety data sheets are an important part of employee training and should be readily accessible.

precautionary information, which must be read and understood by the user before using the product. Also, a list of all hazardous materials used in the shop must be posted for the employees to see.

Shops must also keep records of all training programs, records of accidents or spill incidents, satisfaction of employee requests for specific chemical information via the MSDS, and a general right-to-know compliance procedure manual utilized within the shop.

Hazardous Wastes

WARNING!

When handling any hazardous waste material, be sure to wear the proper safety equipment recommended by the MSDS. Follow all required procedures. This includes the use of approved respirator equipment.

Many repair and service procedures generate **hazardous wastes**, such as dirty solvents. Something is classified as a hazardous waste by the EPA if it is on its list of known harmful materials. A complete EPA list of hazardous wastes can be found in the Code of

Federal Regulations. It should be noted that a material is only considered a hazardous waste when the shop is ready to dispose of it.

Regulations on the generation and handling of hazardous waste have led to the development of equipment found in shops. Examples of these are thermal cleaning units, close-loop steam cleaners, waste oil furnaces, oil filter crushers, refrigerant recycling machines, engine coolant recycling machines, and highly absorbent cloths.

WARNING!

The shop is ultimately responsible for the safe disposal of hazardous waste, even after it leaves the shop. Only licensed waste removal companies should dispose of the waste. In addition to hauling the waste away, they will also take care of all the paperwork, deal with the various government agencies, and advise the shop on how to recover the disposal costs. If there is a hazardous waste spill, contact the National Response Center (1-800-424-8802) immediately. Failure to do so can result in a \$10,000 fine or a year in jail, or both.

Always keep hazardous waste separate from other wastes. Make sure they are properly labeled and sealed in the recommended containers. The storage area should be covered and may need to be fenced and locked if vandalism could be a problem.

Guidelines for Handling Shop Wastes

Some of the common hazardous wastes, along with what you should do with them follows:

Oil Recycle oil. Set up equipment, such as a drip table or screen table with a used-oil collection bucket, to collect oil that drips off parts. Place drip pans underneath vehicles that are leaking fluids onto the storage area. Do not mix other wastes with used oil, except as allowed by your recycler. Used oil generated by a shop (and/or oil received from household do-it-yourself generators) may be burned on site in a commercial space heater. Also, used oil may be burned for energy recovery. Contact state and local authorities to determine requirements and to obtain necessary permits.

Oil Filters Drain for at least 24 hours, crush (**Figure 6-24**) and recycle used oil filters.

Figure 6-24 A hydraulic single oil filter crusher.
Courtesy of SPX Service Solutions

Batteries Recycle batteries by sending them to a reclaimer or back to the distributor. Keeping shipping receipts can demonstrate that you have recycled. Store batteries in a watertight, acid-resistant container. Inspect batteries for cracks and leaks when they come in. Treat a dropped battery as if it were cracked. Acid residue is hazardous because it is corrosive and may contain lead and other toxins. Neutralize spilled acid by covering it with baking soda or lime, and dispose of all hazardous material.

Metal Residue from Machining Collect metal filings when machining metal parts. Keep separate and recycle if possible. Prevent metal filings from falling into a storm sewer drain.

Refrigerants Recover and/or recycle refrigerants during the servicing and disposal of motor vehicle air conditioners and refrigeration equipment. It is not allowable to knowingly vent refrigerants into the atmosphere. Recovery and/or recycling during servicing must be performed by an EPA-certified technician using certified equipment and following specified procedures.

Solvents Replace hazardous chemicals with less toxic alternatives that have equal performance. For example, substitute water-based cleaning solvents for petroleum-based solvent degreasers. To reduce

the amount of solvent used when cleaning parts, use a two-stage process: dirty solvent followed by fresh solvent. Hire a hazardous waste management service to clean and recycle solvents. (Some spent solvents must be disposed of as hazardous waste, unless recycled properly.) Store solvents in closed containers to prevent evaporation. Evaporation of solvents contributes to ozone depletion and smog formation. In addition, the residue from evaporation must be treated as a hazardous waste. Properly label spent solvents and store on drip pans or in diked areas and only with compatible materials.

Containers Cap, label, cover, and properly store aboveground outdoor liquid containers and small tanks within a diked area and on a paved impermeable surface to prevent spills from running into surface or ground water.

Other Solids Store materials such as scrap metal, old machine parts, and worn tires under a roof or tarpaulin to protect them from the elements and to prevent potential contaminated runoff. Consider recycling tires by retreading them.

Liquid Recycling Collect and recycle coolants from radiators. Store transmission fluids, brake fluids, and solvents containing chlorinated hydrocarbons separately, and recycle or dispose of them properly.

Shop Towels/Rags Keep waste towels in a closed container marked “contaminated shop towels only.” To reduce costs and liabilities associated with disposal of used towels, which can be classified as hazardous wastes, investigate using a laundry service that is able to treat the wastewater generated from cleaning the towels.

Asbestos has been identified as a health hazard. *Asbestos* is a term used to describe a number of naturally occurring fibrous materials. It is a carcinogen that causes a number of diseases that result in cancer. Asbestos-caused cancer, or mesothelioma, is a form of lung cancer. When breathed in, the asbestos fibers cause scarring of the lungs and/or damage to the lung’s air passages. The injuries and scars become an effective holding place for the asbestos. Obviously, you want to avoid breathing in asbestos dust and fibers. Be careful when working with asbestos materials, such as brake pads, clutch discs, and some engine gaskets. All asbestos waste must be disposed of in accordance with OSHA and EPA regulations.

For more on work environment safety, contact the U.S. EPA Office of Compliance at <http://es.inel.gov>.

KEY TERMS

Abrasive cleaning	Occupational Safety and Health Administration (OSHA)
Asbestos	Pneumatic tools
Bloodborne pathogens	Power tools
Chemical cleaning	Right-To-Know Laws
Environmental Protection Agency (EPA)	Safety glasses
Hazardous waste	Safety stands
Jack stands	Thermal cleaning
Material safety data sheets (MSDS)	

SUMMARY

- Dressing safely for work is very important. Wear snug-fitting clothing, eye and ear protection, protective gloves, steel-toed shoes, and caps to cover long hair.
- When choosing eye protection, make sure it has safety glass and offers side protection.
- A respirator should be worn whenever you are working around toxic fumes or excessive dust.
- When shop noise exceeds safe levels, protect your ears by wearing earplugs or earmuffs.
- Safety while using any tool is essential, and even more so when using power tools. Before plugging in a power tool, make sure the power switch is off. Disconnect the power before servicing the tool.
- Always observe all relevant safety rules when operating a vehicle lift or hoist. Jacks, jack stands, chain hoists, and cranes can also cause injury if not operated safely.
- Use care whenever it is necessary to move a vehicle in the shop. Carelessness and playing around can lead to a damaged vehicle and serious injury.
- Carbon monoxide (CO) gas is a poisonous gas present in engine exhaust fumes. Exhaust must be properly vented from the shop using tailpipe hoses or other reliable methods.
- Adequate ventilation is also necessary when working with any volatile solvent or material.
- Gasoline and diesel fuel are highly flammable and should be kept in approved safety cans.
- Never light matches near any combustible materials.
- It is important to know when to use each of the various types of fire extinguishers. When fighting a

fire, aim the nozzle at the base and use a side-to-side sweeping motion.

- Right-To-Know Laws came into effect in 1983 and are designed to protect employees who must handle hazardous materials and wastes on the job.
- Material safety data sheets (MSDS) contain important chemical information and must be furnished to all employees annually. New employees should be given the sheets as part of their job orientation.
- All hazardous and asbestos waste should be disposed of according to OSHA and EPA regulations.

REVIEW QUESTIONS

1. What is the correct way to dispose of used oil filters?
2. Where in the shop should a list of emergency telephone numbers be posted?
3. Which of the following offer(s) the least protection for your eyes?
 - a. face shield
 - b. safety glasses
 - c. splash goggles
 - d. prescription glasses
4. Which of the following statements about latex and nitrile gloves is *not* true?
 - a. The gloves offer protection against cuts.
 - b. The gloves offer protection against disease and grease buildup under and around your fingernails.
 - c. Latex gloves are more comfortable but weaken when they are exposed to gas, oil, and solvents.
 - d. Nitrile gloves are not as comfortable but they are not affected by gas, oil, and solvents.
5. Describe the correct process for lifting a heavy object.
6. What are bloodborne pathogens and why should technicians be concerned about them?
7. List at least five things you should remember when using hand tools.
8. List at least five precautions that must be adhered to while working with or around a vehicle's battery.
9. How should a class B fire be extinguished?
10. Where can complete EPA lists of hazardous wastes be found?

11. Which of the following statements about safety glasses is true?
 - a. They should offer side protection.
 - b. The lenses should be made of a shatterproof material.
 - c. Some service operations require that additional eye protection be worn with safety glasses.
 - d. All of the above statements are true.
12. Gasoline is _____.
 - a. highly volatile
 - b. highly flammable
 - c. dangerous, especially in vapor form
 - d. all of the above
13. Technician A says that it is recommended that you wear shoes with nonslip soles in the shop. Technician B says that steel-toed shoes offer the best foot protection. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
14. Technician A says that used engine coolant should be collected and recycled. Technician B says that all oil-based waste materials can be collected in the same container if an approved waste disposal company is hired to rid the shop of the oil. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
15. There are many ways to clean parts while they are being serviced. These methods can be grouped into three separate categories. What are they?
16. Federal Right-To-Know Laws concern _____.
 - a. auto emission standards
 - b. hazards associated with chemicals used in the workplace
 - c. employee benefits
 - d. hiring practices
17. Which of the following is/are important when working in an automotive shop?
 - a. using the proper tool for the job
 - b. avoiding loose-fitting clothes
 - c. wearing steel-toed shoes
 - d. all of the above
18. Technician A says that the volatility of a substance is a statement of how easily the substance vaporizes or explodes. Technician B says that the flammability of a substance is a statement of how well the substance supports combustion. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
19. Which of the following is *not* recommended for use when trying to extinguish flammable liquid fires?
 - a. foam
 - b. carbon dioxide
 - c. water
 - d. dry chemical
20. List at least five precautions that must be adhered to while working on a vehicle with a high-voltage system.
21. What is the correct procedure for using a fire extinguisher to put out a fire?
22. Technician A ties his long hair behind his head while working in the shop. Technician B covers her long hair with a brimless cap. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
23. Technician A uses compressed air to blow dirt from his clothes and hair. Technician B uses compressed air to clean off the top of a workbench. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
24. Heavy protective gloves should be worn when _____.
 - a. welding
 - b. grinding metal
 - c. working with caustic cleaning solutions
 - d. all of the above
25. Proper disposal of oil filters includes _____.
 - a. recycling used filters
 - b. draining them for at least 24 hours
 - c. crushing them
 - d. all of the above

PREVENTIVE MAINTENANCE AND BASIC SERVICES

OBJECTIVES

- Describe the information that should be included on a repair order.
- Explain how repair costs can be estimated.
- Explain how the vehicle and its systems can be defined by deciphering its VIN.
- Explain the importance of preventive maintenance, and list at least six examples of typical preventive maintenance.
- Understand the differences between the fluids required for preventive maintenance and know how to select the correct one for a particular vehicle.
- Explain how the design of a vehicle determines what preventive maintenance procedures must be followed.

Preventive services are those services performed not to correct problems but rather to prevent them. These and other basic services are covered in this chapter. All of these services may be performed by technicians in many different types of service facilities—dealerships, independents, and specialty shops. Regardless of what type of shop, the first thing a tech needs to worry about is the repair order.

REPAIR ORDERS

A **repair order (RO)** is written for every vehicle brought into the shop for service. ROs may also be called service or work orders. ROs contain information about the customer, the vehicle, the customer's concern or request, an estimate of the cost for the services, and the time the services should be completed (**Figure 7-1**). ROs are legal documents that are used for many other purposes, such as payroll and general record keeping (**Figure 7-2**). Legally, an RO protects the shop and the customer.

Although every shop may enter different information onto the original RO, most ROs contain the following information:

- Complete customer information
- Complete vehicle identification
- The service history of the vehicle
- The customer's complaint
- The preliminary diagnosis of the problem

- An estimate of the amount of time required for the service
- An estimate of the costs of the parts involved in the service
- The time the services should be completed
- The name or other identification of the technician assigned to perform the services
- The actual services performed with their cost
- The parts replaced during the services
- Recommendations for future services
- The total cost of the services

Figure 7-1 Service facilities run smoothly when there is good communications between the customer and the technician.

Copyright 2009 Cengage Learning, Inc. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part.

An RO is signed by the customer, who in doing so authorizes the service and accepts the terms noted on the RO. The customer also agrees to pay for the services when they are completed. Many states require a customer signature to begin repair work and for a change in the original estimate. If a signature is not required for changes in the original estimate, all phone conversations concerning the estimate should be noted on the RO.

In most cases when a customer signs the RO, he or she acknowledges the shop's right to impose a mechanic's lien. This lien basically says that the shop may gain possession of the vehicle if the customer does not pay for the agreed-upon services and the vehicle remains at the shop for a period of 90 or more days. This clause ensures that the shop will receive some compensation for the work performed, whether or not the customer pays the bill.

After the work has been completed and the RO filed, it becomes a legal service record. Service records are kept by the shop to maintain the vehicle's service history and for legal purposes. Evidence of repairs and recommended repairs is very important for settling potential legal disputes with the vehicle's owner in the future.

Computerized Shop Management Systems

Today, most service facilities use computerized shop management software. The information for the completion of an RO is input on the computer's keyboard. The software package also helps in the estimation of repair costs. The software also takes information from the RO and saves it in various files. These files are used for many purposes, such as schedule reminders, bookkeeping, vehicle/owner history, and tracking employee productivity. Notes can also be added to the RO (these do not appear on the RO). These personal notes can be used to remind the shop of commitments made to the customer, any special information about the customer and/or the vehicle, and any abnormal events that took place during the customer's last visit to the shop.

When the customer arrives at the shop, the computer can quickly recall all pertinent information about the vehicle. Typically, all the service writer needs to do is key in the vehicle's license number, the vehicle's identification number, or the owner's name. If the customer has been to the shop before, all information will be available to the service writer. Also, most shop management software relies on numerical codes to denote what services have been and will be performed. These codes serve as shortcuts so the service writer

does not need to key in the description of each service. The codes are designated by the software company or the vehicle's manufacturer. At a dealership, these link directly to the warranty reimbursement file.

Parts Replacement

Very often when a service is performed, parts are replaced. This appears on the RO as "R&R," which stands for "remove and replace." In a dealership, nearly all of the replacement parts are original equipment manufacturer (OEM) parts obtained through the parts department. Some replacement parts installed by a dealership and nearly all parts installed by other service facilities are from the aftermarket. Other replacement parts may be rebuilt or remanufactured units. These are based on parts that have failed and have been rebuilt or restored to specifications. Normally, remanufactured parts are totally tested, disassembled, cleaned, and machined, and all of the weak or dysfunctional parts replaced. If this process is completed correctly, the remanufactured part will be as reliable as an original equipment (OE) part.

Parts that are destined to be rebuilt have a value to them. Therefore, when they are replaced, the original (replaced) part has a core value and the customer is charged a "core charge." The replaced part is called a **core**, because it is the basis for rebuilding. The core charge represents the value of the failed part. Core charges are built into the RO and can be negated when the shop or customer returns the core. Core charges are typical for replacement engines, transmissions, starters, generators, and brake shoes.

If the replaced part has no core value, the shop disposes of the part. However, many shops offer the part to the customer as proof that the part was removed and a new one installed. At times, the customer will insist that the part be given them. Always place the part in plastic or another container before putting it inside the vehicle. This will prevent any dirt on the part from getting on anything inside the vehicle.

Sublet Repairs

Service facilities typically do not perform all possible services. Often another business will be contracted to perform a service or part of the service. This is referred to as subletting. **Sublet repairs** are sent to shops that specialize in certain repairs, such as radiator repairs. Often a repair, or part of the repair, is performed by another person or company outside the dealership or service facility. The cost of the subletting is added to the costs of the services performed by the service facility. Often the customer is billed slightly more than the actual cost of the sublet repair.

When estimating the cost of a repair or service:

- Make sure you have the correct contact information for the customer.
- Make sure you have the correct information about the vehicle.
- Always use the correct labor and parts guide or database for that specific vehicle.
- Locate the exact service for that specific vehicle in the guide or database.
- Using the guidelines provided in the guide or database, choose the proper time allocation listed for the service.
- Multiply the allocated time by the shop's hourly labor rate.
- If any sublet repairs are anticipated, list this service as a sublet repair and add the cost to the labor costs.
- Using the information given in the guide or database, identify the parts that will be replaced for that service.
- Locate the cost of the parts in the guide or database or in the catalogs used by the shop.
 - Repeat the process for all other services required or requested by the customer.
 - Multiply the time allocations by the shop's hourly flat rate.
 - Add all of the labor costs together; this sum is the labor estimate for those services.
 - Add the cost of all the parts together; this sum is the estimate for the parts required for the services.
 - Add the total labor and parts costs together. If the shop charges a standard fee for shop supplies, add it to the labor and parts total. This sum is the cost estimate to present to the customer.

Figure 7-3 Guidelines for estimating the cost of repairs.**Estimating Repair Costs**

For legal reasons and to establish good customer relations, estimated repair costs must be calculated with as much accuracy as possible. The customer is protected against being charged more than the estimate given on the RO, unless he or she later authorizes a higher amount. Some states allow shops to be within 10% of the estimate, whereas others hold the shop to the amount that was estimated. **Figure 7-3** lists some things to follow when estimating the cost of services and repairs.

VEHICLE IDENTIFICATION

Before any service is done to a vehicle, it is important for you to know exactly what type of vehicle you are working on. The best way to do this is to refer to

the **vehicle's identification number (VIN)**. The VIN is given on a plate behind the lower corner of the driver's side of the windshield as well as other locations on the vehicle. The VIN is made up of seventeen characters and contains all pertinent information about the vehicle. The use of the seventeen number and letter code became mandatory beginning with 1981 vehicles and is used by all manufacturers of vehicles both domestic and foreign. Most new vehicles have a scan code below the VIN (**Figure 7-4**).

Each character of a VIN has a particular purpose. The first character identifies the country where the vehicle was manufactured; for example:

- 1 or 4 – U.S.A.
- 2 – Canada

**Figure 7-4** A vehicle identification plate.

- 3 – Mexico
- J – Japan
- K – Korea
- S – England
- W – Germany

The second character identifies the manufacturer; for example:

- A – Audi
- B – BMW
- C – Chrysler
- D – Mercedes Benz
- F – Ford
- G – General Motors
- H – Honda
- N – Nissan
- T – Toyota

The third character identifies the vehicle type or manufacturing division (passenger car, truck, bus, and so on). The fourth through eighth characters identify the features of the vehicle, such as the body style, vehicle model, and engine type.

The ninth character is used to identify the accuracy of the VIN and is a check digit. The tenth character identifies the model year; for example:

- S – 1995
- V – 1997
- W – 1998
- Y – 2000
- 1 – 2001
- 3 – 2003
- 5 – 2005
- 7 – 2007
- 9 – 2009

The eleventh character identifies the plant where the vehicle was assembled, and the twelfth to seventeenth characters identify the production sequence of the vehicle as it rolled off the manufacturer's assembly line.

PREVENTIVE MAINTENANCE

Preventive maintenance (PM) involves performing certain services to a vehicle on a regularly scheduled basis before there is any sign of trouble. Regular inspection and routine maintenance can prevent

major breakdowns and expensive repairs. It also keeps cars and trucks running efficiently and safely.

A recent survey of 2,375 vehicles conducted during National Car Care Month found that more than 90% of the cars looked at needed some form of service. The cars were inspected for exhaust emissions, fluid levels, tire pressure, and other safety features. The results indicated that 34% of the cars had restricted air filters; 27% had worn belts; 25% had clogged PCV filters; 14% had worn hoses; and 20% had bad batteries, battery cables, or terminals.

During the fluid and cooling system inspection, 39% failed due to bad or contaminated transmission or power steering fluid, 36% had worn-out or dirty engine oil, 28% had inadequate cooling system protection, and 8% had a faulty radiator cap.

In the safety category, 50% failed due to worn or improperly inflated tires, 32% had inoperative headlights or brake lights, and 14% had worn wipers.

A typical PM schedule recommends particular service at mileage or time intervals. Driving habits and conditions should also be used to determine the frequency of PM service intervals. For example, vehicles that frequently are driven for short distances in city traffic may require more frequent oil changes due to the more rapid accumulation of condensation and unburned fuel in the oil. Most manufacturers also specify more frequent service intervals for vehicles that are used to tow a trailer or those that operate in extremely dusty or unusual conditions.

Safety Inspections

Several states and provinces require annual or biennial vehicle safety inspections. The intent of these inspections is to improve road safety. Research shows that states with annual safety inspection programs have 20% fewer accidents than states without safety inspections. These inspections consist of a series of safety-related checks of various systems and areas of a vehicle. For example, some common checks are shown in **Figure 7–5**. The exact systems and subsystems that are inspected vary. The inspections are part of the vehicle registration process. Often automobile dealers are required to complete a safety inspection on all used vehicles before they are sold and report the results to the customer.

INSPECT WINDSHIELD AND OTHER GLASS FOR:

- Cloudiness, distortion, or other obstruction to vision.
- Cracked, scratched, or broken glass.
- Window tinting.
- Operation of front door glass.

INSPECT WINDSHIELD WIPER/WASHER FOR:

- Operating condition.
- Condition of blade.

INSPECT WINDSHIELD DEFROSTER FOR:

- Operating condition.

INSPECT MIRRORS FOR:

- Rigidity of mounting.
- Condition of reflecting surface.
- View of road to rear.

INSPECT HORN FOR:

- Electrical connections, mounting, and horn button.
- Emits a sound audible for a minimum of 200 feet.

INSPECT DRIVER'S SEAT FOR:

- Anchorage.
- Location.
- Condition.

INSPECT SEAT BELTS FOR:

- Condition.

INSPECT HEADLIGHTS FOR:

- Approved type, aim, and output.
- Condition of wiring and switch.
- Operation of beam indicator.

INSPECT OTHER LIGHTS FOR:

- Operation of all lamps, lens color, and condition of lens.
- Aim of fog and driving lamps.

INSPECT SIGNAL DEVICE FOR:

- Correct operation of indicators (visual or audible).
- Illumination of all lamps, lens color, and condition of lens.

INSPECT FRONT DOORS FOR:

- Handle or opening device permits the opening of the door from the outside and inside of the vehicle.
- Latching system that holds door in its proper closed position.

INSPECT HOOD FOR:

- Operating condition of hood latch.

INSPECT FLUIDS FOR:

- Levels that are below the proper level.

INSPECT BELTS AND HOSES FOR:

- Belt tension, wear, or absence.
- Hose damage.

INSPECT POLLUTION CONTROL SYSTEM FOR:

- Presence of emissions system—evidence that no essential parts have been removed, rendered inoperative, or disconnected.

INSPECT BATTERY FOR:

- Proper anchorage.
- Loose or damaged connections.

INSPECT FUEL SYSTEM FOR:

- Any part that is not securely fastened.
- Liquid fuel leakage.
- Fuel tank filler cap for presence.

INSPECT EXHAUST SYSTEM FOR:

- Damaged exhaust—manifold, gaskets, pipes, mufflers, connections, etc.
- Leakage of gases at any point from motor to point discharged from system.

INSPECT STEERING AND SUSPENSION FOR:

- Play in steering wheel.
- Wear in bushings, kingpins, ball joints, wheel bearings, tie-rod ends.
- Looseness of gear box on frame, condition of drag link, and steering arm.
- Wheel alignment and axle alignment.
- Broken spring leaves and worn shackles.
- Shock absorbers.
- Broken frame.
- Broken or missing engine mounts.
- Lift blocks.

INSPECT FLOOR PAN FOR:

- Holes that allow exhaust gases to enter occupant compartment.
- Conditions that create a hazard to the occupants.

INSPECT BRAKES FOR:

- Worn, damaged, or missing parts.
- Worn, contaminated, or defective linings or drums.
- Leaks in system and proper fluid level.
- Worn, contaminated, or defective disc pads or discs.
- Excessive pedal play.

INSPECT PARKING BRAKE FOR:

- Proper adjustment.

INSPECT TIRES, WHEELS, AND RIMS FOR:

- Proper inflation.
- Loose or missing lug nuts.
- Condition of tires, including tread depth.
- Mixing radials and bias ply tires.
- Wheels that are cracked or damaged so as to cause unsafe operation.

Figure 7-5 A safety inspection may include these items.

BASIC SERVICES

The services required for a PM program are generally noncorrective procedures. However, often while performing PM on a vehicle, a technician notices the need for a minor repair. Both PM and those basic minor services are covered in the rest of this chapter.

Customer Care

Whenever you do any service to a vehicle, use fender covers (Figure 7-6) and do not leave fingerprints on the exterior or interior of the car. If oil or grease gets on the car, clean it off.

Engine Oil

Engine oil is a clean or refined form of **crude oil**. Crude oil, when taken out of the ground, is dirty and does not work well as a lubricant for engines. Crude oil must be refined to meet industry standards. Engine oil (often called motor oil) is just one of the many products that come from crude oil. Engine oil is specially formulated so that it:

- Can flow easily through the engine
- Provides lubrication without foaming
- Reduces friction and wear
- Prevents the formation of rust and corrosion
- Cools the engine parts it flows over
- Keeps internal engine parts clean

Engine oil contains many additives, each intended to improve the effectiveness of the oil. The **American Petroleum Institute (API)** classifies engine oil as

Figure 7-6 Fender covers should be used when working under the hood.

TABLE 7-1 ENGINE OIL SERVICE RATINGS

RATING	COMMENTS
SA	Straight mineral oil (no additives), not suitable for use in any engine
SB	Non-detergent oil with additives to control wear and oil oxidation
SC	Obsolete since 1964
SD	Obsolete since 1968
SE	Obsolete since 1972
SF	Obsolete since 1980
SG	Obsolete since 1988
SH	Obsolete since 1993
SJ	Obsolete since 1997

standard or S-class for passenger cars and light trucks and as commercial or C-class for heavy-duty commercial applications. The various types of oil within each class are further rated according to their ability to meet the engine manufacturers' warranty specifications (**Table 7-1**). Engine oils can be classified as **energy-conserving** (fuel-saving) **oils**. These are designed to reduce friction, which in turn reduces fuel consumption. Friction modifiers and other additives are used to achieve this.

In addition to the API rating, oil **viscosity** is important in selecting engine oil. The ability of oil to resist flowing is its viscosity. The thicker the oil, the higher its viscosity rating. Viscosity is affected by temperature; hot oil flows faster than cold oil. Oil flow is important to the life of an engine. Because an engine operates under a wide range of temperatures, selecting the correct viscosity is very important.

The **Society of Automotive Engineers (SAE)** has established an oil viscosity classification system that is accepted throughout the industry. This system is a numeric rating in which the higher viscosity, or heavier weight, oils receive the higher numbers. For example, oil classified as SAE 50 weight oil is heavier and flows slower than SAE 10 weight oil. Heavyweight oils are best suited for use in high-temperature regions. Low-weight oils work best in low-temperature operations.

Figure 7-7 The SAE classification and the API rating are displayed in this way on a container of oil.

Although single viscosity oils are available, most engine oils are **multiviscosity** oils. These oils carry a combined classification such as 10W-30. This rating says the oil has the viscosity of both a 10- and a 30-weight oil. The “W” after the 10 notes that the oil’s viscosity was tested at 0°F (−18°C). This is commonly referred to as the “winter grade.” Therefore, the 10W means the oil has a viscosity of 10 when cold. The 30 rating is the hot rating. This rating was the result of testing the oil’s viscosity at 212°F (100°C). To formulate multiviscosity oils, polymers are blended into the oil. Polymers expand when heated. With the polymers, the oil maintains its viscosity to the point where it is equal to 30-weight oil. The SAE classification and the API rating are displayed on the container of oil (**Figure 7-7**).

ISLAC Oil Ratings The International Lubrication Standardization and Approval Committee (ISLAC) has developed an oil rating that combines SAE viscosity ratings and the API service rating. If engine oil meets the standards, a “sunburst” symbol is displayed on the container (**Figure 7-8**). This means the oil is suitable for use in nearly any gasoline engine.

SHOP TALK

Many engines have very specific requirements. Always install the type of oil specified by the manufacturer. Never assume that a particular type of oil can be used in an engine.

Figure 7-8 The ISLAC certification mark, commonly referred to as “the Starburst.”

Synthetic Oils Synthetic oils are considered synthetic because the finished product does not occur naturally and it was made through a chemical, not natural, process. The introduction of synthetic oils dates back to World War II. Synthetic oils have many advantages over mineral oils, including better fuel economy and engine efficiency by reducing friction; they have low viscosity in low temperatures and a higher viscosity in warm temperatures, and they tend to have a longer useful life. Synthetic oils cost much more than mineral oils, which is the biggest drawback for using them. Engine oils that are blends of mineral oils and synthetics to keep the cost down are available but offer many of the advantages of synthetic oil.

Maintenance Perhaps the PM service that is best known to the public is changing the engine’s oil and filter. Because oil is the lifeblood of an engine, it is critical that the oil and filter are changed on a regular basis. Photo Sequence 3 shows the steps involved in changing the engine oil and oil filter. Whenever doing this, make sure the oil is the correct rating for the vehicle.

In between oil and filter changes, the level of the oil should be periodically checked. When doing this, make sure the vehicle is parked on level ground. Locate and remove the oil **dipstick**. With a clean rag, wipe the oil from the dipstick and reinsert it all the way in its tube. Remove it again and check the level of the oil (**Figure 7-9**). If the level is at the “full” mark, the level is okay. If the level is at the “add” mark, this means the level is about 1 quart low. Regardless of the level, examine the oil for evidence of dirt. If the oil is contaminated, it must be changed.

Figure 7-9 Check the engine’s oil level with the dipstick.

Changing the Oil and Oil Filter

P3-1 Always make sure the vehicle is positioned safely on a lift or supported by jack stands before working under it. Before raising the vehicle, allow the engine to run awhile. After it is warm, turn off the engine.

P3-2 The tools and other items needed to change the engine's oil and oil filter are rags, a funnel, an oil filter wrench, safety glasses, and a wrench for the drain plug.

P3-3 Place the oil drain pan under the drain plug before beginning to drain the oil.

P3-4 Loosen the drain plug with the appropriate wrench. After the drain plug is loosened, quickly remove it so the oil can freely drain from the oil pan.

P3-5 Make sure the drain pan is positioned so it can catch all of the oil.

P3-6 While the oil is draining, use an oil filter wrench to loosen and remove the oil filter.

P3-7 Make sure the oil filter seal came off with the filter. Then place the filter into the drain pan so it can drain. After it has completely drained, discard the filter according to local regulations.

P3-8 Wipe off the oil filter sealing area on the engine block. Then apply a coat of clean engine oil onto the new filter's seal.

P3-9 Install the new filter and hand-tighten it. Oil filters should be tightened according to the directions given on the filter.

Changing the Oil and Oil Filter (*continued*)

P3-10 Prior to installing the drain plug, wipe off its threads and sealing surface with a clean rag.

P3-11 Tighten the drain plug according to the manufacturer's recommendations. Overtightening can cause thread damage, whereas undertightening can cause an oil leak.

P3-12 With the oil filter and drain plug installed, lower the vehicle and remove the oil filler cap.

P3-13 Carefully pour the oil into the engine. The use of a funnel usually keeps oil from spilling on the engine.

P3-14 After the recommended amount of oil has been put in the engine, check the oil level.

P3-15 Start the engine and allow it to reach normal operating temperature. While the engine is running, check the engine for oil leaks, especially around the oil filter and drain plug. If there is a leak, shut down the engine and correct the problem.

P3-16 After the engine has been turned off, recheck the oil level and correct it as necessary.

Cooling System

Whenever you change an engine's oil, you should also do a visual inspection of the different systems under the hood, including the cooling system. Inspect all cooling system hoses for signs of leakage and/or damage. Replace all hoses that are swollen, cracked, or show signs of leakage. The radiator should also be checked for signs of leaks; if any are evident the radiator should be repaired or replaced. Also, check the front of the radiator for any buildup of dirt and bugs (**Figure 7-10**). This can restrict airflow through the radiator and should be removed by thorough cleaning.

The level and condition of the engine's coolant should also be checked. Check the coolant's level at the coolant recovery tank (**Figure 7-11**). It should be between the "low" and "full" lines. If the level is too low, more coolant should be added through the cap of the tank, not the radiator. Bring the level up to the "full" line. Always use the correct type of coolant when topping off or replacing it. Look at the color of the coolant when checking the level. It should be green, or perhaps orange, but it should not look rusty or cloudy. If the coolant looks contaminated,

Figure 7-11 The level of coolant in the cooling system should be checked at the coolant recovery tank.

the cooling system should be flushed and new coolant put into the system.

SHOP TALK

Recycle all used antifreeze/coolant or take it to an authorized collection point. Do not dump old coolant into a sewage drain, the ground, or any body of water.

Figure 7-10 A buildup of dirt and bugs can restrict airflow through the radiator.

CAUTION!

Never remove the radiator cap when the coolant is hot. Because the system is pressurized, the coolant can be hotter than boiling water and will cause severe burns. Wait until the top radiator hose is not too hot to touch. Then press down on the cap and slowly turn it until it hits the first stop. Now slowly let go of the cap. If there is any built-up pressure in the system, it will be released when the cap is let up. After all pressure has been exhausted, turn the radiator cap to remove it.

Coolant Engine **coolant** is a mixture of water and antifreeze/coolant. Water alone has a boiling point of 212°F (100°C) and a freezing point of 32°F (0°C) at sea level. A mixture of 67% antifreeze and 33% water will raise the boiling point of the mixture to 235°F (113°C) and lower the freezing point to -92°F (-69°C). As can be seen in **Figure 7-12**, antifreeze in excess of 67% will actually raise the freezing point of the mixture. Normally, the recommended mixture is a 50/50 solution of water and antifreeze/coolant. Some coolant suppliers offer a mixture of pure water and

Figure 7-12 The relationship of the percentage of antifreeze in the coolant to the coolant's freezing and boiling points.

antifreeze that can be used to top off a cooling system when the level is low (**Figure 7-13**).

The antifreeze concentration must always be a minimum of 44% all year and in all climates. If the percentage is lower than 44%, engine parts may be eroded by cavitation, and cooling system components may be severely damaged by corrosion.

Five types of coolant are commonly available:

- **Ethylene glycol**—This is the most commonly used antifreeze/coolant. It is green in color and provides good protection regardless of climate, but it is poisonous.

Figure 7-13 Topping off the cooling system with a 50/50 mixture of antifreeze and water.

CAUTION!

Never leave ethylene glycol or propylene glycol coolant out and lying around. Both children and animals will drink it because of its sweet taste. The coolant is poisonous and can cause death.

- **Propylene glycol**—This type has the same basic characteristics as ethylene glycol-based coolant but is not sweet tasting and is less harmful to animals and children. Propylene glycol-based coolants should not be mixed with ethylene glycol.
- **Phosphate-free**—This is ethylene glycol-based coolant that has no phosphates, which makes it more environmentally friendly. Phosphate-free coolant is recommended by some auto manufacturers.
- **Organic acid technology (OAT)**—This coolant is also environmentally friendly and contains zero phosphates or silicones. This orange coolant is often referred to by a brand name “DEX-COOL” and is used in all late-model GM vehicles (**Figure 7-14**).
- **Hybrid organic acid technology (HOAT)**—This is similar to OAT coolant but has been enhanced with additives that make the coolant less abrasive to water pumps.

Coolant Condition A coolant hydrometer is used to check the amount of antifreeze in the coolant. This tester contains a pickup hose, coolant reservoir, and squeeze bulb. The pickup hose is placed in the

Figure 7-14 Ethylene glycol is the most commonly used antifreeze/coolant and is green in color. OAT coolant is orange and is often referred to by a brand name “DEX-COOL.”

Figure 7-15 A refractometer that tests coolant condition and battery electrolyte.

radiator coolant. When the squeeze bulb is squeezed and released, coolant is drawn into the reservoir. As coolant enters the reservoir, a pivoted float moves upward with the coolant level. A pointer on the float indicates the freezing point of the coolant on a scale located on the reservoir housing.

A refractometer (**Figure 7-15**) offers a precise way to check coolant condition. Most refractometers can also measure the specific gravity of battery electrolyte and test the condition of brake fluid. A sample of the fluid is placed in the sample area of the meter and as light passes through the sample, a line is cast on the meter's scale. The line shows the concentration of the antifreeze in the coolant (**Figure 7-16**).

Test strips are also used to gain a precise evaluation of coolant. The test strips are immersed into a sample of coolant. After about 5 minutes the strip will change color. The color of the strip is then compared to a scale on the container of strips. Matching the

colors will indicate the freeze protection level and the acidity of the coolant (**Figure 7-17**).

Drive Belts

Drive belts have been used for many years. **V-belts** and **V-ribbed** (serpentine) **belts** are used to drive water pumps, power steering pumps, air-conditioning compressors, generators, and emission control pumps (**Figure 7-18**). Heat has adverse effects on drive belts and they tend to overcure due to excessive heat. This causes the rubber to harden and crack. Excessive heat normally comes from slippage. Slippage can be caused by improper belt tension or oily conditions. When there is slippage, heat also travels through the drive pulley and down the shaft to the support bearing of the component it is driving. These bearings may be damaged if the slippage is allowed to continue.

V-belts ride in a matching groove in the engine's pulleys. The angled sides of the belt contact the inside of the pulleys' grooves (**Figure 7-19**). This point of contact is where motion is transferred. As a V-belt wears, it begins to ride deeper in the groove. This reduces its tension and promotes slippage. Because this is a normal occurrence, periodic adjustment of belt tension is necessary.

Drive belts can be used to drive a single part or a combination of parts. An engine can have three or more V-belts. In some cases, two matched belts are used on the same pulley set. This increases the strength of the belt and pulley connection and provides redundancy in case a belt breaks.

Most late-model vehicles use a **serpentine belt** to drive all or most accessories. Serpentine belts are long and follow a complex path that weaves around the

1. Place a few drops of the sample fluid on the measuring prism and close the cover.

2. Hold up to a light and read the scale.

Figure 7-16 Measuring antifreeze and battery electrolyte levels with a refractometer.

Figure 7-17 Matching the color of a test strip to the scale on its container will indicate the freeze protection level and the acidity of the coolant.

Figure 7-18 A V-belt rides in a single groove, whereas a V-ribbed belt rides in several grooves.

Figure 7-19 The sides of a V-belt contact the grooves of the pulleys.

various pulleys (**Figure 7-20**). Proper tension is critical on a serpentine belt due to the complex routing. Serpentine belts are flat on the outside and have a series of continuous ribs on the inside. These ribs fit into matching grooves in the pulleys. Both the ribbed side and the flat side of the belt can be used to transfer power. Over time, the belts will stretch and lose their tension. To compensate for this and to keep a proper amount of belt tension, most serpentine belt systems

Figure 7-20 A serpentine drive belt. *Courtesy of Gates Corporation*

Figure 7-21 A belt tensioner for a serpentine belt. *Courtesy of Gates Corporation*

have a belt tensioner pulley. This pulley is a spring-loaded pulley (**Figure 7-21**) that exerts a predetermined amount of the pressure on the belt to keep it at the desired tension.

Figure 7-22 Drive belts should be inspected.
Courtesy of Chrysler LLC

If a belt does not have the proper tension, it may squeal or chirp, it may roll off a pulley, or it may slip. Excessive tension may put unwanted forces on the pulleys and the shafts they are attached to, leading to noise, belt breakage, glazing, and damage to the bearings and bushings in the driven components.

Inspection Even the best drive belts last only an average of 4 years. That time can be shortened by several things; most of these can be found by inspecting the belts. Check the condition of all of the drive belts on the engine. Carefully look to see if they have worn or glazed edges, tears, splits, and signs of oil soaking (**Figure 7-22**). If these conditions exist, the belt should be replaced. Also inspect the grooves of the drive pulleys for rust, oil, wear, and other damage. If a pulley is damaged, it should be replaced. Rust, dirt, and oil should be cleaned off the pulley before installing a new belt.

Misalignment of the pulleys reduces the belt's service life and brings about rapid pulley wear, which causes thrown belts and noise. Undesirable side or end thrust loads can also be imposed on pulley or pump shaft bearings. Check alignment with a straight-edge. Pulleys should be in alignment within $\frac{1}{16}$ inch (1.59 mm) per foot of the distance across the face of the pulleys.

Belt Tension A quick check of a belt's tension can be made by locating the longest span of the belt between two pulleys. With the engine off, press on the belt

Figure 7-23 Check the tension of a drive belt with a belt tension gauge.

midway through that distance. If the belt moves more than $\frac{1}{2}$ inch per foot of free span, the belt should be adjusted. Keep in mind that different belts require different tensions. The belt's tension should be checked with a belt tension gauge (**Figure 7-23**). The tension should meet the manufacturer's specifications. Many engines are now equipped with a ribbed V-belt, which has an automatic tensioning pulley; therefore, a tension adjustment is not required.

USING SERVICE INFORMATION

Proper belt tightening procedures and specifications are given in the specification section of most service manuals.

The exact procedure for adjusting belt tension depends on what the belt is driving. Normally, the mounting bracket for the component driven by the belt and/or its tension adjusting bolt is loosened. The mounting brackets on generators, power steering pumps, and air compressors are designed to be adjustable. Some brackets have a hole or slot to allow the use of a prybar. Other brackets have a $\frac{1}{2}$ -inch square opening in which a breaker bar can be installed to move the component and tighten the belt. Other engines have an adjusting bolt, sometimes called a jackscrew, that can be tightened to correct the belt tension. Loosen the mounting bolts and hold the component in the position that provides for the correct tension. Be careful not to damage the part you are prying against. Then tighten the mounting bolts or tension adjusting bolt to keep the tension on the belt. Once tightened, recheck the belt tension with the tension gauge.

Figure 7-24 The size and part number of a new belt are given on the belt container. The size can be verified by physically comparing the old with the new belt.

Belt Replacement If a drive belt is damaged, it should be replaced. If there is more than one drive belt, all should be replaced even if only one is bad. Always use an exact replacement belt. The size of a new belt is typically given, along with the part number, on the belt container (**Figure 7-24**). You can verify that the new belt is a replacement for the old one by physically comparing the two. This, however, does not account for any belt stretch that may have occurred. Therefore, only use this comparison as verification. The best way to select the correct replacement belt is with a parts catalog and/or by matching the numbers on the old belt to the numbers on the new belt.

To replace a V-belt on some engines, it may be necessary to remove the fan, fan pulley, and other accessory drive belts to gain access to belts needing replacement. Also, before removing the old drive belt, disconnect the electric cooling fan at the radiator, if the vehicle has one. Remove the old belt by loosening the components that have adjusting slots for belt tension. Then slip the old belt off. Check the condition and alignment of the pulleys. Correct any problems before installing the new belt. Place the new belt around the pulleys. Once in place, loosely tighten the bolts that were loosened during belt removal. Then adjust the tension of the belt and retighten all mounting hardware.

SHOP TALK

It is never advisable to pry a belt onto a pulley. Obtain enough slack so the belt can be slipped on without damaging either the V-belts or a pulley. Some power steering pumps have a ½-inch drive socket to aid in adjusting belts to the proper tension without prying against any accessory.

Photo Sequence 4 shows the correct procedure for inspecting, removing, replacing, and adjusting a V-ribbed belt. Before removing a serpentine belt, locate a belt routing diagram in a service manual or on an underhood decal. Compare the diagram with the routing of the old belt. If the actual routing is different from the diagram, draw the existing routing on a piece of paper.

After installation of a new belt, the engine should be run for 10 to 15 minutes to allow belts to seat and reach their initial stretch condition. Modern steel-strengthened V-belts do not stretch much after the initial run-in, but it is often recommended that the tension of the belt be rechecked after 5,000 miles (8,000 km).

Air Filters

If an air filter is doing its job, it will get dirty. This is why filters are made of pleated paper. The paper is pleated to increase the filtering area. By increasing the area, the amount of time it will take for dirt to plug the filter becomes longer. As a filter gets dirty, the amount of air that can flow through it is reduced. This is not a problem until less air than what the engine needs can get through the filter. Without the proper amount of air, the engine will not be able to produce the power it should; nor will it be as fuel efficient as it should be.

Included in the PM plan for all vehicles is the periodic replacement of the air filter. This mileage or time interval is based on normal vehicle operation. If the vehicle is used, or has been used, in heavy dust, the life of the filter is shorter. Always use a replacement filter that is the same size and shape as the original. An air filter should be periodically checked for excessive dirt or blockage (**Figure 7-25**). The best way to do this is to remove it and hold it up against a light. If little

Figure 7-25 A dirty and a clean air filter.

Typical Procedure for Inspecting, Removing, Replacing, and Adjusting a Drive Belt

P4-1 *Inspect the belt by looking at both sides.*

P4-2 *Look for signs of glazing.*

P4-3 *Look for signs of tearing or cracking.*

P4-4 *To replace a worn belt, locate the tensioner or generator pulley.*

P4-5 *Loosen the hold-down fastener for the tensioner or generator pulley.*

P4-6 *Pry the tensioner or generator pulley inward to release the belt tension and remove the belt.*

P4-7 *Match the old belt up for size with the new replacement belt.*

P4-8 *Observe the belt routing diagram in the engine compartment.*

Typical Procedure for Inspecting, Removing, Replacing, and Adjusting a Drive Belt *(continued)*

P4-9 Install the new belt over each of the drive pulleys. Often the manufacturer recommends a sequence for feeding the belt around the pulleys.

P4-10 Pry out the tensioner or generator pulley to put tension on the belt.

P4-11 Install the belt squarely in the grooves of each pulley.

P4-12 Measure the belt deflection in its longest span. If a belt tension gauge is available, use it and compare the tension to specifications.

P4-13 Pry the tensioner or generator pulley to adjust the belt to specifications.

P4-14 Tighten the tensioner or generator pulley fastener.

P4-15 Start the engine and check the belt for proper operation.

or no light passes through the filter, it should be replaced. Air filters are typically replaced every 30,000 miles (50,000 km).

When replacing the filter element, carefully remove all dirt from the inside of the housing. Large pieces of dirt and stones accumulate here. It would be disastrous if that dirt got into the cylinders. Also make sure that the air cleaner housing is properly aligned and closed around the filter to ensure good airflow of clean air. If the filter does not seal well in the housing, dirt and dust can be pulled into the air-stream to the cylinders. The shape and size of the air filter element depends on its housing; the filter must be the correct size for the housing or dirt will be drawn into the engine.

Battery

The battery is the main source of electrical energy for the vehicle. It is very important that it is inspected and checked on a regular basis.

SHOP TALK

It should be noted that disconnecting the battery on late-model cars removes some memory from the engine's computer and the car's accessories. Besides losing the correct time on its clock or the programmed stations on the radio, the car might run roughly. If this occurs, allow the engine to run for a while before shutting it off.

PROCEDURE

1. Visually inspect the battery cover and case for dirt and grease.
2. Check the electrolyte level (if possible).
3. Inspect the battery for cracks, loose terminal posts, and other signs of damage.
4. Check for missing cell plug covers and caps.
5. Inspect all cables for broken or corroded wires, frayed insulation, or loose or damaged connectors.
6. Check the battery terminals, cable connectors, metal parts, holdowns, and trays for corrosion damage or buildup—a bad connection can cause reduced current flow.
7. Check the heat shield for proper installation on vehicles so equipped.

If the battery or any of the associated parts are dirty (**Figure 7-26**) or corroded, they should be removed and cleaned. Photo Sequence 5 shows the

Figure 7-26 A really dirty battery.

correct procedure for cleaning a battery, a battery tray, and battery cables.

SHOP TALK

When removing or installing a battery, always use the built-in battery strap or a battery lifting tool to lift the battery in or out of its tray.

Transmission Fluid

The oil (**Figure 7-27**) used in automatic transmissions is called **automatic transmission fluid (ATF)**. This special fluid is dyed red so that it is not easily confused with engine oil. Before checking the fluid,

Figure 7-27 Automatic transmission fluid (ATF).

Typical Procedure for Cleaning a Battery Case, Tray, and Cables

P5-1 Loosen the battery negative terminal clamp.

P5-2 Use a terminal clamp puller to remove the negative cable.

P5-3 Loosen the battery positive terminal clamp.

P5-4 Use a terminal clamp puller to remove the positive clamp.

P5-5 Remove the battery hold-down hardware and any heat shields.

P5-6 Remove the battery from the tray.

P5-7 Mix a solution of baking soda and water.

P5-8 Brush the baking soda solution over the battery case, but do not allow the solution to enter the cells of the battery.

P5-9 Flush the baking soda off with water.

Typical Procedure for Cleaning a Battery Case, Tray, and Cables *(continued)*

P5-10 Use a scraper and wire brush to remove corrosion from the hold-down hardware.

P5-11 Brush the baking soda solution over the hold-down hardware and then flush with water.

P5-12 Allow the hardware to dry, then paint it with corrosion-proof paint.

P5-13 Use a terminal cleaner brush to clean the battery cables.

P5-14 Use a terminal cleaner brush to clean the battery posts.

P5-15 Install the battery back into the tray. Also install the hold-down hardware.

P5-16 Install the positive battery cable. Then install the negative cable.

Figure 7-28 Automatic transmission fluid should be checked regularly. Normally the level is checked when the engine is warm. The normal cold level is well below the normal hot level.

make sure the engine is warm and the vehicle is level. Then set the parking brake and allow the engine to idle. Sometimes the manufacturer recommends that the ATF level be checked when the transmission is placed into Park; however, some may require some other gear. Make sure you follow those requirements. Locate the fluid dipstick (normally located to the rear of the engine) and pull it out of its tube. Check the level of the fluid on the dipstick (**Figure 7-28**). If the level is low, add only enough to bring the level to full. Make sure you only use the fluid recommended by the manufacturer.

The condition of the fluid should be checked while checking the fluid level. The normal color of ATF is pink or red. If the fluid has a dark brownish or blackish color and/or a burned odor, the fluid has been overheated. A milky color indicates that engine coolant has been leaking into the transmission's cooler in the radiator.

After checking the ATF level and color, wipe the dipstick on absorbent white paper and look at the stain left by the fluid. Dark particles are normally band and/or clutch material, whereas silvery metal particles are normally caused by the wearing of the transmission's metal parts. If the dipstick cannot be wiped clean, it is probably covered with varnish, which results from fluid oxidation. Varnish will cause the transmission's valves to stick, causing improper shifting speeds. Varnish or other heavy deposits indicate the need to change the transmission's fluid and filter.

The exact fluid that should be used in an automatic transmission depends on the transmission design and the year the transmission was built. It is very important that the correct type of ATF be used. Always refer to the service or owner's manual for the correct type of fluid to use. Some transmission dipsticks are also marked with the type of ATF required.

Although there are many types of ATF available, the following are the most common:

- **ATF +3 (Chrysler Specification MS-7176E)**—This is a fluid formulated for Chrysler automatic transmissions where ATF+, ATF+2, or ATF +3 is recommended.
- **Type F**—This fluid is typically recommended for Ford and some imported vehicle automatic transmissions built prior to the 1977 model year as well as some 1977 through 1982 models. Do not assume that all Ford vehicles use type F; they do not and it has been a long time since they did!
- **Dexron® VI/Mercon®**—This fluid is sometimes referred to as multipurpose ATF because it is recommended for all GM and Ford automatic transmissions (since 1983) requiring Dexron or Mercon transmission fluids. It also is suitable for most Mercedes-Benz passenger car automatic transmissions.
- **Multivehicle ATF**—This ATF is specially formulated to meet the requirements of a broad range of automatic transmission specifications. It can be safely used in most U.S. vehicles but should not be used in a few pre-1986 vehicles where type F fluids are specified, in vehicles requiring Dexron VI, or in some recent vehicles equipped with continuous variable transmissions (CVTs).

Some transmissions require the use of fluids not mentioned here. CVTs require a fluid that is much different from that used in automatic transmissions. Always use the fluid recommended by the manufacturer. The use of the wrong fluid may cause the transmission to operate improperly and/or damage the transmission.

Manual Transmissions Manual transmissions, transaxles, and drive axle units require the use of specific lubricants or oils, and the levels need to be checked according to the manufacturer's recommended service intervals. Some manufacturers recommend that the fluids be changed periodically. Most repair shops have an air-operated dispenser for these fluids; others rely on a hand-operated oil pump (**Figure 7-29**).

Power-Steering Fluid

Now locate the power-steering pump. The level of power-steering fluid is checked with the engine off. The filler cap on the power-steering pump normally has a dipstick. Unscrew the cap and check the level (**Figure 7-30**). The level of the fluid is normally checked when the engine is warm. If the fluid is cold,

Figure 7-29 A hand-operated pump used to fill transmissions and drive axles with lubricant.

Figure 7-30 The filler cap on a power-steering pump normally has a dipstick to check the fluid level.

it will read lower than normal. Add fluid as necessary. Sometimes the fluid used in these systems is ATF; check the service manual for the proper fluid type before adding fluid.

Brake Fluid

Brake fluid levels are checked at the master cylinder. Older master cylinders are made of cast iron or aluminum and have a metal bail that snaps over the master cylinder cover to hold it in place. Normally the bail can be moved in only one direction. Once moved out of the way, the master cylinder cover can be removed. Once removed, the fluid levels can be checked.

Figure 7-31 Translucent brake fluid reservoirs allow the fluid level to be observed from the outside.

Newer master cylinders have a metal or plastic reservoir mounted above the cylinder. The reservoir will have one or two caps. To check the fluid level in the metal reservoir, the cap must be removed. Most often the caps are screwed on. The caps on some plastic reservoirs have snaps to hold them. Unsnap the cap to check the fluid. It is important to clean the area around the caps before removing them. This prevents dirt from falling into the reservoir. A rubber diaphragm attached to the inside of the caps is designed to stop dirt, moisture, and air from entering into the reservoir. Make sure the diaphragm is not damaged.

Most new plastic reservoirs are translucent and allow the fluid level to be observed from the outside (**Figure 7-31**).

While checking the fluid level, look at the color of the fluid. Brake fluid tends to absorb moisture and its color gives clues as to the moisture content of the fluid. Dark- or brown-colored fluid indicates contamination; the system must be flushed and the fluid replaced.

When it is necessary to add brake fluid, make sure the fluid is the correct type and is fresh and clean. There are basically four types of brake fluids: DOT 3, DOT 4, DOT 5, and DOT 5.1 (**Figure 7-32**). The specifications for all automotive brake fluids are defined by Society of Automotive Engineers (SAE) Standard J1703 and Federal Motor Vehicle Safety Standard (FMVSS) 116. Fluids classified according to FMVSS 116 are assigned Department of Transportation (DOT) numbers. Basically, the higher the DOT number, the more rigorous the specifications for the fluid. Domestic automakers specify DOT 3 fluid for their vehicles. However, Ford calls for a heavy-duty variation, which meets the basic specifications for

Figure 7-32 The three types of brake fluid: DOT 3 is the most commonly used.

DOT 3 but has the higher boiling point of DOT 4. Import manufacturers are about equally divided between DOT 3 and DOT 4.

DOT 3, DOT 4, and DOT 5.1 fluids are polyalkylene-glycol-ether mixtures, called “**polyglycol**” for short. The color of both DOT 3 and DOT 4 fluid ranges from clear to light amber. DOT 5 fluids are all silicone based because only silicone fluid—so far—can meet the DOT 5 specifications. No vehicle manufacturer, however, recommends DOT 5 fluid for use in its brake systems. Although all three fluid grades are compatible they do not combine well if mixed together in a system. Therefore, the best rules are to use the fluid type recommended by the manufacturer and to never mix fluid types in a system.

Clutch Fluid On some vehicles with a manual transmission, there is another but smaller master cylinder close to the brake master cylinder. This is the clutch master cylinder. Its fluid level needs to be checked, which is done in the same way as brake fluid. In most cases, the clutch master cylinder uses the same type of fluid as the brake master cylinder. However, check this out before adding any fluid.

Windshield Wipers

Check the condition of the windshield wipers. Wiper blades can become dull, torn, or brittle. If they are, they should be replaced. Also, check the condition of the wiper arms. Look for signs of distortion or damage. Also, check the spring on the arm. This spring is designed to keep the wiper blade fairly tight against the windshield. If the spring is weak or damaged, the blade will not do a respectable job cleaning the glass.

Most wiper blade assemblies have replaceable blades or inserts (**Figure 7-33**). To replace the blades, grab hold of the assembly and pivot it away from the

Figure 7-33 Windshield wiper blades are replaced as a complete assembly, or blade inserts are fitted into the blade.

Figure 7-34 Examples of the different ways that wiper blade inserts are secured to the blade assembly. Courtesy of Federal-Mogul Corporation

windshield. Once the arm is moved to its maximum position, it should stay there until it is pivoted back to the windshield. Doing this will allow you to easily replace the wiper blades without damaging the vehicle's paint or glass.

There are three basic types of wiper blade inserts (**Figure 7-34**). Look carefully at the old blade to determine which one to install. Remove the old insert and install the new one. After installation, pull on the insert to make sure it is properly secured. If the insert comes loose while the wipers are moving across the windshield, the wiper arm could scratch the glass.

Most often wiper blades are replaced as an assembly. There are several methods used to secure the blades to the wiper arm (**Figure 7-35**). Most

Figure 7-35 Examples of the different ways windshield wiper blades are secured to the wiper arm.
Courtesy of Chrysler LLC

replacement blades come with the necessary adapters to secure the blade to the arm.

When it is necessary to replace the wiper arm or the entire assembly, they must be removed. Wiper arms are either mounted onto a threaded shaft and held in place by a nut, or they are pressed over a splined shaft. Some shaft-mounted arms are held in place by a clip that must be released before the arm can be pulled off. When installing wiper arms, make sure they are positioned so the blades do not hit the frame of the windshield while they are operating. When checking the placement and operation of the wipers, wet the windshield before turning on the wipers. The water will serve as a lubricant for the wipers.

Windshield Washer Fluid The last fluid level to check is the windshield washer fluid (**Figure 7-36**). Visually check the level and add as necessary. Always use windshield washer fluid and never add water to the washer fluid reservoir, especially in cold weather. The water can freeze and crack the tank or clog the washer hoses and nozzles.

Tires

The vehicle's tires should be checked for damage and wear. Tires should have at least $\frac{1}{16}$ " of tread remaining. Any less and the tire should be replaced. Tires have "tread wear indicators" molded into them. When the wear bar shows across the width of the tread, the tire is worn beyond its limits. Most shops use a tire wear gauge, which gives an accurate measurement of the tread depth (**Figure 7-37**). Also, check the tires for

Figure 7-36 Check the level of the windshield washer fluid at the reservoir.

Figure 7-37 A tire tread depth gauge.

bulges, nails, tears, and other damage. All of these indicate the tire should be replaced.

Inflation Check the inflation of the tires. To do this, use a tire pressure gauge (**Figure 7-38**). Press the gauge firmly onto the tire's valve stem. The air pressure in the tire will push the scale out of the tool. The highest number shown on the scale is the air pressure of the tire. Compare this reading with the specifications for the tire.

Figure 7-38 Check the tires and wheels for damage and proper inflation.

SEE OWNER'S MANUAL FOR MORE INFORMATION.					

Front, rear, and
spare tire pressures

Figure 7-39 The tire placard gives the recommended cold tire pressure for that vehicle.

The correct tire pressure is listed in the vehicle's owner's manual or on a decal (placard) stuck on the driver's doorjamb (**Figure 7-39**). The air pressure rating on the tire is not the amount of pressure the tire should have. Rather this rating is the maximum pressure the tire should ever have when it is cold.

New vehicles are fit with tire inflation monitoring systems. These systems have an air pressure sensor attached to the inside of each wheel. When the pressure is below or above a specified range, the vehicle's computer causes a warning light on the dash to illuminate. This alerts the driver of a problem. These monitors can be, and should be, checked, because tire pressure is important to the safety of the vehicle's occupants, and false monitor readings can cause many hardships.

Tire Rotation To equalize tire wear, most car and tire manufacturers recommend that the tires be rotated. Front and rear tires perform different jobs and can

Figure 7-40 Rotation sequence for radial tires.

wear differently, depending on driving habits and the type of vehicle. In an RWD vehicle, for instance, the front tires usually wear along the outer edges, primarily because of the scuffing and slippage encountered in cornering. The rear tires wear in the center because of acceleration thrusts. To equalize wear, it is recommended that tires be rotated as illustrated in **Figure 7-40**. Bias ply and bias-belted tires should be rotated about every 6,000 miles. Radial tires should be initially rotated at 7,500 miles and then at least every 15,000 miles thereafter. It is important that directional tires are kept rotating in the direction they are designed for. This means the tires may need to be dismounted from the wheel, flipped, and reinstalled on the rim before being put on the other side of the car.

Lug Nut Torque Obviously, to rotate the tires you must remove the tire/wheel assemblies and then reinstall them. Before reinstalling a tire/wheel assembly on a vehicle, make sure the wheel studs are clean and not damaged, then clean the axle/rotor flange and wheel bore with a wire brush or steel wool. Coat the axle pilot flange with disc brake caliper slide grease or an equivalent. Place the wheel on the hub. Install the lug nuts, and tighten them alternately to draw the wheel evenly against the hub. They should be tightened to a specified torque (**Figure 7-41**) and sequence to avoid distortion. Many tire technicians snug up the lug nuts, then when the car is lowered to the floor, they use a torque wrench for the final tightening.

WARNING!

Overtorquing of the lug nuts is the most common cause of disc brake rotor distortion. Also, an overtightened lug distorts the threads of the lug and could lead to premature failure.

Figure 7-41 Wheel lugs should be tightened to the specified torque.

Figure 7-42 Torque sticks are color coded to indicate their torque setting.

Some technicians use a torque absorbing adapter, also called a torque stick (**Figure 7-42**), to tighten the lug nuts. Make sure you use the correct stick for the recommended torque. Then check the actual torque of the lug nuts with a torque wrench.

Chassis Lubrication

A PM procedure that is becoming less common because of changing technology is chassis lubrication. However, all technicians should know how to do this. During the lubrication procedure, grease is forced between two surfaces that move or rub against each other. The grease reduces the friction produced by the movement of the parts. During a chassis lube, grease is forced into a pivot point or joint through a grease fitting. Grease fittings are found on steering and suspension parts, which need lubrication to prevent wear and noise caused by their action during vehicle operation.

Grease fittings are called **zerk fittings** and are threaded into the part that should be lubricated. A fit-

ting at the end of a manual or pneumatic grease gun fits over the zerk to inject the lubricant. Older vehicles have zerk fittings in many locations, whereas newer vehicles use permanently lubricated joints. Some of these joints have threaded plugs that can be removed to lubricate the joint. A special adapter is threaded onto the grease gun and into the plug's bore to lubricate the joint. After grease has been injected into the joint, the plug should be reinstalled or a zerk fitting installed. On some vehicles, rubber or plastic plugs are installed at the factory; they should never be reused.

Before lubricating the chassis, refer to the service manual and identify the lubrication points for the vehicle. Then raise the vehicle. Locate the lubrication points and wipe the fittings clean with a shop towel. Zerk fittings have a one-way spring-loaded check valve that allows grease into the joint but prevents it from leaking out. Dirt can plug the valve, allowing grease to leak out and water and dirt to leak in.

Carefully look at the joints to see if the joint boots are sealed or not. Some joints, such as tie-rod ends and ball joints, are sealed with rubber boots. If the boots are good, push the grease gun's nozzle straight onto a zerk fitting and pump grease slowly into the joint (**Figure 7-43**). If the joint has a sealed boot, put just enough grease into the joint to cause the boot to slightly expand. If the boot is not sealed, put in enough grease to push the old grease out. Then wipe off the old grease and any excess grease. Repeat this at all lubrication points.

Greases Greases are made from oil blended with thickening agents. There are a few synthetic greases available that meet the same standards as petroleum greases. The thickening agent increases the viscosity

Figure 7-43 A grease gun forces lubrication into a joint through a zerk fitting.

NLGI Grade	Worked Penetration	
	after 60 strokes at 77°F(25°C)	Appearance
000	44.5–47.5 mm	fluid
00	4.00–4.30 mm	fluid
0	3.55–3.85 mm	very soft
1	3.10–3.40 mm	soft
2	2.65–2.95 mm	moderately soft
3	2.20–2.50 mm	semifluid
4	1.75–2.05 mm	semihard
5	1.30–1.60 mm	hard
6	0.85–1.15 mm	very hard

Figure 7-44 The table shows the NLGI grades and the worked penetration ranges.

of the grease. Greases are categorized by a **National Lubricating Grease Institute (NLGI)** number and by the thickeners and additives that are in the grease, such as lithium, molybdenum disulfide, calcium, aluminum, barium, or sodium. Some greases are also labeled with an “EP,” which means they have extreme pressure additives. The number assigned by the NLGI is based on test results and the specifications set by the American Society for Testing Materials (ASTM).

The ASTM specifies the consistency of grease using a penetration test. During this test, the grease is heated to 77°F (25°C) and placed below the tip of the test cone. The cone is dropped into the grease. The distance the cone is able to penetrate the grease is measured. The cone will penetrate deeper into soft grease. The NLGI number represents the amount of penetration (**Figure 7-44**). The higher the NLGI number, the thicker the grease is. NLGI #2 is typically specified for wheel bearings and chassis lubrication.

The NLGI also specifies grease by its use and has established two categories for automotive use. Chassis lubricants are identified with the prefix “L,” and

Class	Purpose
GA	Mild duty—wheel bearings
GB	Mild to moderate duty—wheel bearings
GC	Mild to severe duty—wheel bearings
LA	Mild duty—chassis parts and universal joints
LB	Mild to severe duty—chassis parts and universal joints

Figure 7-45 ASTM grease designation guide.

wheel bearing lubricants have a prefix of “G.” Greases are further defined within those groups by their overall performance. Chassis greases are classified as either LA or LB, and there are three classifications for wheel bearing greases (GA, GB, and GC). LB and GC have the highest performance ratings and are the greases specified for chassis and wheel bearing lubrication. Many types of greases are labeled as both GC and LB and are acceptable for both. These are often referred to as multipurpose greases (**Figure 7-45**). The NLGI certification mark is included on the grease’s container (**Figure 7-46**).

HYBRID VEHICLES

Hybrid vehicles are maintained and serviced in the same way as conventional vehicles, except for the hybrid components. The latter includes the high-voltage battery pack and circuits, which must be respected when doing any service on the vehicles. Other services to hybrid vehicles are normal services that must be completed in a different way.

For the most part, service to the hybrid system is not something that is done by technicians, unless they are certified to do so by the automobile manufacturer. Keep in mind that a hybrid has nearly all of the basic systems as a conventional vehicle and these are diagnosed and serviced in the same way. Through

Figure 7-46 NLGI identification symbols.

Figure 7-47 An example of some of the warning lights in a hybrid vehicle.

an understanding of how the hybrid vehicle operates, you can safely service them.

One of the things to pay attention to is the stop-start feature. You need to know when the engine will normally shut down and restart. Without this knowledge, or the knowledge of how to prevent this, the engine may start on its own when you are working under the hood. Needless to say, this can create a safety hazard. There is a possibility that your hands or something else can be trapped in the rotating belts or hit by a cooling fan. Unless the system is totally shut down, the engine may start at any time when its control system senses that the battery needs to be recharged.

In addition, there is a possibility that the system will decide to power the vehicle by electric only. When it does this, there is no noise, just a sudden movement of the vehicle. This can scare you and can be dangerous. To prevent both of these incidences, always remove the key from the ignition. Make sure the “READY” lamp in the instrument cluster is off; this lets you know the system is also off (**Figure 7-47**).

Maintenance

Maintenance of a hybrid vehicle is much the same as a conventional one. Care needs to be taken to avoid anything orange while carrying out the maintenance procedures.

The computer-controlled systems are extremely complex, especially in assist and full hybrids, and are very sensitive to voltage changes. This is why the manufacturers recommend a thorough inspection of the auxiliary battery and connections every 6 months.

The engines used in hybrids are modified versions of engines found in other models offered by the manufacturer. Other than fluid checks and changes, there is little maintenance required on these engines. However, there is less freedom in deciding the types of fluids that can be used and the parts that can replace the original equipment. Hybrids are not very forgiving. Always use the exact replacement parts and the fluids specified by the manufacturer.

Typically, the weight of the engine oil used in a hybrid is very light. If heavier oil is used, the computer may see this as a problem and prevent the engine from starting. The heavier oil may cause an increase in the current required to crank the engine. If the computer senses very high current draw while attempting to crank the engine, it will open the circuit in response.

Special coolants are required in most hybrids because the coolant cools not only the engine, but also the inverter assembly. Cooling the inverter is important and checking its coolant condition and level is an additional check during PM. The cooling systems used in some hybrids feature electric pumps and storage tanks (**Figure 7-48**). The tanks store heated coolant and can cause injury if you are not aware of how to carefully check them.

The battery cooling system may need to be serviced at regular intervals. There is a filter in the ductwork from the outside of the vehicle to the battery box. This filter needs to be periodically changed. If the filter becomes plugged, the temperature of the battery will rise to dangerous levels. In fact, if the computer senses high temperatures it may shut down the system.

Figure 7-48 The hot coolant storage tank for Toyota hybrids.

A normal part of PM is checking power steering and brake fluids. The power steering systems used by the manufacturers vary; some have a belt-driven pump, some have an electrically driven pump, and others have a pure electric and mechanical steering gear. Each variety requires different care; therefore, always check the service manual for the specific model before doing anything to these systems. Also, keep in mind that some hybrids use the power steering pump as the power booster for the brake system.

Hybrids are all about fuel economy and reduced emissions. Everything that would affect these should be checked on a regular basis. Items such as tires, brakes, and wheel alignment can have a negative effect, and owners of hybrids will notice the difference. These owners are constantly aware of their fuel mileage due to the displays on the instrument panel.

ADDITIONAL PM CHECKS

The following PM checks are in addition to those items specified by the manufacturer. These should be performed at these suggested time intervals to help ensure safe and dependable vehicle operation.

Time: While operating the vehicle

- Pay attention to and note any changes in the sound of the exhaust or any smell of exhaust fumes in the vehicle.
- Check for vibrations in the steering wheel. Notice any increased steering effort or looseness in the steering wheel.
- Notice if the vehicle constantly turns slightly or pulls to one side of the road.

- When stopping, listen and check for strange sounds, pulling to one side, increased brake pedal travel, or hard-to-push brake pedal.
- If any slipping or changes in the operation of the transmission occur, check the transmission fluid level.
- Check for fluid leaks under the vehicle. (Water dripping from the air-conditioning system after use is normal.)
- Check the automatic transmission's park function.
- Check the parking brake.

Time: At least monthly

- Check the operation of all exterior lights, including the brake lights, turn signals, and hazard warning flashers.

Time: At least twice a year

- Check the pressure in the spare tire.
- Check headlight alignment.
- Check the muffler, exhaust pipes, and clamps.
- Inspect the lap/shoulder belts for wear.
- Check the radiator, heater, and air-conditioning hoses for leaks or damage.

Time: At least once a year

- Lubricate all hinges and all outside key locks.
- Lubricate the rubber weather strips for the doors.
- Clean the body's water drain holes.
- Lubricate the transmission controls and linkage.

SUMMARY

- A repair order (RO) is a legal document used for many purposes.
- An RO includes a cost estimate for the repairs. By law, this estimate must be quite accurate.
- Preventive maintenance (PM) involves regularly scheduled service on a vehicle to keep it operating efficiently and safely. Professional technicians should stress the importance of PM to their customers.
- Engine oil is a clean or refined form of crude oil. It contains many additives, each intended to improve the effectiveness of the oil.
- The American Petroleum Institute (API) classifies engine oil according to its ability to meet the engine manufacturers' warranty specifications.
- The Society of Automotive Engineers (SAE) has established an oil viscosity classification system that has a numeric rating in which the higher viscosity, or heavier weight oils, receives the higher numbers.
- Changing the engine's oil and filter should be done on a regular basis.
- Whenever the engine's oil is changed, a thorough inspection of the cooling systems should be done.
- Normally, the recommended mixture for engine coolant is a 50/50 solution of water and antifreeze/coolant.
- V-belts and V-ribbed (serpentine) belts are used to drive water pumps, power steering pumps, air-conditioning compressors, generators, and emission control pumps.
- If a belt does not have the proper tension, it may produce squealing and chirping noises; allow the belt to roll off a pulley; or slip, which reduces the power that drives the component.
- Excessive belt tension may put unwanted forces on the pulleys and the shafts they are attached to, leading to noise, belt breakage, glazing, and damage to the bearings and bushings in water pumps, generators, and power steering pumps.
- The air filter should be periodically checked for excessive dirt or blockage and a replacement filter should be the same size and shape as the original.
- The battery is the main source of electrical energy for the vehicle. It is very important that it is checked on a regular basis.
- If the battery or any of the associated parts are dirty or corroded, remove the battery and clean them.
- The condition of the automatic transmission fluid (ATF) should be checked while checking the fluid level.
- Normally the fluid used in power-steering systems is ATF. Check the service manual for the proper fluid type before adding fluid.
- Check the level of the brake fluid and make sure the fluid is the correct type and is fresh and clean.
- There are basically four types of brake fluids: DOT 3, DOT 4, DOT 5, and DOT 5.1. Most automakers specify DOT 3 fluid for their vehicles.
- Check the windshield wipers for signs of dullness, tears, and hardness. Also check the spring on the wiper arm.
- The vehicle's tires should be checked for damage and wear as well as for proper inflation.
- To equalize tire wear, most car and tire manufacturers recommend that the tires be rotated after a specified mileage interval.
- Several parts of a vehicle may need periodic lubrication; always use the correct type of grease when doing this.
- Some PM procedures are unique to hybrid vehicles; always follow the recommendations of the manufacturer.
- When servicing a hybrid vehicle, always respect its high-voltage system.

REVIEW QUESTIONS

1. Describe the information found in a VIN.
2. Technician A stresses the need to follow the manufacturer's recommendations for preventive maintenance to his customers. Technician B says that the proper PM service intervals depends on the customer's driving habits and typical driving conditions. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
3. Technician A says that tires should have a tread depth of at least $\frac{1}{16}$ of an inch. Technician B says that tires have a tread wear indicator built into them. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B

4. When working on a hybrid electric vehicle, which of the following statements does *not* reflect things you should be aware of?
 - a. The engine will normally shut down and restart when stopped.
 - b. The engine may start at any time when its control system senses that the battery needs to be recharged.
 - c. The system may decide to power the vehicle, while it is parked, by the engine anytime the load is great.
 - d. Make sure the “READY” lamp in the instrument cluster is off; this lets you know the system is off.
5. *True or False?* Legally, an RO protects the shop and the customer.
6. While examining the color of an engine’s coolant: Technician A says that because it is orange, the cooling system should be flushed and new coolant put into the system. Technician B says that the coolant looks rusty and the cooling system should be flushed and new coolant put into the system. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
7. While checking the condition of a vehicle’s ATF: Technician A says that if the fluid has a dark brownish or blackish color, the fluid has been overheated. Technician B says that a milky color indicates that engine coolant has been leaking into the transmission’s cooler in the radiator. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
8. Technician A says that if a drive belt does not have the proper tension, it may produce squealing and chirping noises. Technician B says that excessive tension may cause noise, belt breakage, and glazing. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
9. List five things that engine oil is formulated to do.
10. Technician A says that the rubber diaphragm attached to the inside of the master cylinder caps is designed to stop dirt from entering the reservoir. Technician B says that the rubber diaphragm is designed to stop air from entering the reservoir. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
11. Why should you wipe off the outside of a zerk fitting before injecting grease into it?
12. *True or False?* All engine coolants contain some phosphates, which make them unfriendly to the environment.
13. List at least five things that should be checked while inspecting a vehicle’s battery.
14. *True or False?* If brake fluid is dark or brown colored, the system must be flushed and the fluid replaced.
15. Which of the following statements about drive belt slippage is *not* true?
 - a. Excessive heat normally comes from slippage.
 - b. As a V-belt slips, it begins to ride deeper in the pulley groove.
 - c. Slippage can be caused by improper belt tension or oily conditions.
 - d. When there is slippage, heat travels through the drive pulley and down the shaft to the support bearing of the component it is driving.
16. *True or False?* ATF labeled as “Multivehicle ATF” can safely be used in all automatic transmissions.
17. Which of the following statements about an oil’s viscosity is *not* true?
 - a. The ability of oil to flow is its viscosity.
 - b. Viscosity is affected by temperature; hot oil flows faster than cold oil. Oil flow is important to the life of an engine.
 - c. In the API system of oil viscosity classification, the lighter oils receive a higher number.
 - d. Heavyweight oils are best suited for use in high-temperature regions. Low-weight oils work best in low temperature operations.
18. While discussing the readings on a built-in hydrometer in a battery: Technician A says that the green dot means the battery is charged enough for testing. Technician B says that the red dot means the battery is completely discharged and must be replaced. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
19. Which of the following is *not* a true statement about a mechanic’s lien?
 - a. This lien states that the shop may gain possession of the vehicle if the customer does not pay for the agreed-upon services.

- b. The right to impose a mechanic's lien can be exercised by a shop within 30 days after the services have been completed.
 - c. In most cases, the shop's right to impose a lien on the vehicle being serviced must be acknowledged by the customer prior to beginning any services to the vehicle.
 - d. This clause ensures that the shop will receive some compensation for the work performed, whether or not the customer pays the bill.
20. *True or False?* An oil with the classification of 5W-30 has the viscosity of both a 10- and 30-weight oil. The 5W means the oil has a viscosity of 5 when warm and a 30 rating when it is cold.
21. While discussing the effects of overtorquing wheel lugs: Technician A says that this can cause the threads of the lugs and/or studs to distort. Technician B says that this is the most common cause of disc brake rotor distortion. Who is correct?
- a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
22. The most commonly used brake fluid in domestic vehicles is:
- a. DOT 2
 - b. DOT 3
 - c. DOT 4
 - d. DOT 5
23. Which of the following greases are best suited for lubricating automotive wheel bearings?
- a. LA
 - b. LB
 - c. GA
 - d. GC
24. While discussing the special preventive maintenance items for a hybrid vehicle: Technician A says that special coolants are required in most hybrids because the coolant not only cools the engine, but also the inverter assembly. Technician B says that the battery cooling system may have a filter in the ductwork from the outside of the vehicle to the battery box and that this filter needs to be periodically changed. Who is correct?
- a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
25. How does a technician determine the proper inflation of a vehicle's tires?

BASIC THEORIES AND MATH

OBJECTIVES

- Describe the states in which all matter exists. ■ Explain what energy is and how energy is converted.
- Calculate the volume of a cylinder. ■ Explain the forces that influence the design and operation of an automobile. ■ Describe and apply Newton's laws of motion to an automobile. ■ Define friction and describe how it can be minimized. ■ Describe the various types of simple machines. ■ Explain the difference between torque and horsepower. ■ Differentiate between a vibration and a sound.
- Explain Pascal's law and give examples of where it is applied to an automobile. ■ Explain the behavior of gases. ■ Explain how heat affects matter. ■ Describe what is meant by the chemical properties of a substance. ■ Explain the difference between oxidation and reduction. ■ Describe the origin and practical applications of electromagnetism.

This chapter contains many of the things you have learned or will learn in other courses. The material is not intended to take the place of those other courses but rather to emphasize the knowledge you need to gain employment and be successful in an automotive career. Many of the facts presented in this chapter will be addressed again in greater detail according to the topic. Make sure you understand the contents of this chapter.

MATTER

Matter is anything that occupies space. All matter exists as a gas, liquid, or solid. Gases and liquids are considered fluids because they move or flow easily and easily respond to pressure. A gas has neither a shape nor volume of its own and tends to expand without limits. A liquid takes a shape and has volume. A solid is matter that does not flow.

Atoms and Molecules

All matter is made up of countless tiny particles called **atoms**. A substance with only one type of atom is referred to as an **element**. Over 100 elements are known to exist; 92 occur naturally and the rest have been manufactured in laboratories (**Figure 8-1**). The atom is the smallest particle of an element and has all of the chemical characteristics of the element.

Small, positively charged particles called protons are located in the center, or nucleus, of each atom. In most atoms, the nucleus also contains neutrons. Neutrons have no electrical charge, but they add weight to the atom. The positively charged protons tend to repel each other, and this repelling force could destroy the nucleus. The presence of the neutrons with the protons cancels the repelling action and keeps the nucleus together. Electrons are small, very light particles with a negative electrical charge. Electrons move in orbits around the atom's nucleus. Elements are listed on the atomic scale, or periodic chart, according to their number of protons and electrons. For example, hydrogen is number 1 on this scale, and copper is number 29.

A proton is about 1,840 times heavier than an electron. Therefore, electrons are easier to move than protons. While the electrons are orbiting, centrifugal force tends to move them away from the nucleus. However, the attraction between the positively charged protons and the negatively charged electrons holds the electrons in their orbits.

Atoms of different elements have different numbers of protons, electrons, and neutrons. Some of the lighter elements have the same number of protons and neutrons, but many of the heavier elements have more neutrons than protons.

Figure 8-1 The periodic table of the elements with each element's natural state shown.

A hydrogen (H) atom is the simplest atom. It has one proton and one electron (**Figure 8-2**). A copper (Cu) atom has 29 protons and 29 electrons. The electrons orbit in four different rings around the nucleus. Because two, eight, and eighteen electrons are the maximum number of electrons in the first three electron rings next to the nucleus, the fourth ring has one electron (**Figure 8-3**). The outer ring of electrons is called the valence ring, and the number of electrons in the valence ring determines the electrical characteristics of the element.

A single atom of some elements does not exist. An example of this is oxygen, whose symbol is O. Pure oxygen exists only as a pair of oxygen atoms and has a symbol of O₂. This is a molecule of oxygen. A **molecule** is the smallest particle of an element or compound. A molecule can be made of one type or different types of atoms. A compound contains two or more different types of atoms. Oxygen atoms readily combine with atoms of other elements to form a compound. Many other atoms also have this same characteristic.

**Figure 8-2** A hydrogen atom has one proton (red), one neutron (yellow), and one electron (green).**Figure 8-3** A copper atom.

Figure 8-4 A molecule of water.

Water is a compound of oxygen and hydrogen atoms. The chemical symbol for water is H_2O . This symbol indicates that each molecule of water contains two atoms of hydrogen and one atom of oxygen (Figure 8-4).

Ions

An **ion** is an atom or molecule that has lost or gained one or more electrons. As a result, it has a negative or positive electrical charge. A negatively charged ion has more electrons than it has protons. The opposite is true of positively charged ions, which have fewer electrons than protons. Ions are denoted in the same way as other atoms and molecules except for a superscript symbol or number that shows the electrical charge and the number of electrons gained or lost. For example, hydrogen with a positive charge (H^+) and oxygen with a negative charge (O^{2-}) is called an **oxide**.

Plasma Considered by scientists as the fourth state of matter, **plasma** refers to an ionized gas that has about an equal amount of positive ions and electrons. The electrons travel with the nucleus of the atoms but can move freely and are not bound to it. The gas at this point no longer behaves as a gas. It now has electrical properties and creates a magnetic field, which radiates light and other forms of electromagnetic energy. It typically takes the form of gaslike clouds and is the basis of most stars. In fact, our sun is really just a large piece of plasma. Plasmas are the most common form of matter in the universe. Plasma in the stars and in the space between them occupies nearly 99% of the visible universe.

Plasma does not exist as a solid, liquid, or gas; it is different and has a much different temperature range. Plasma is more dense than other states of matter.

Behavior of the States

The particles of a solid are held together in a rigid structure. When a solid dissolves into a liquid, its particles break away from this structure and mix evenly

in the liquid, forming a **solution**. When they are heated, most liquids **evaporate**, which means atoms or molecules break free from the body of the liquid to become gas particles. When all of the liquid has evaporated, a solid is left behind. The particles of the solid are normally arranged in a structure called a crystal.

Absorption and Adsorption Not all solids dissolve in a liquid; rather, the liquid is either absorbed or adsorbed. The action of a sponge is the best example of absorption. When a dry sponge is put into water, the water is absorbed by the sponge. The sponge does not dissolve; the water merely penetrates into the sponge and the sponge becomes filled with water. There is no change to the atomic structure of the sponge, nor does the structure of the water change. If we take a glass and put it into water, the glass does not absorb the water. The glass, however, still gets wet as a thin layer of water adheres to the glass. This is adsorption. Materials that *absorb* fluids are **permeable** substances. **Impermeable** substances, such as glass, *adsorb* fluids. Some materials are impermeable to most fluids, whereas others are impermeable to just a few.

ENERGY

Energy may be defined as the ability to do work. Because all matter consists of atoms and molecules in constant motion, all matter has energy. Energy is not matter, but it affects the behavior of matter. Everything that happens requires energy, and energy comes in many forms.

Each form of energy can change into other forms. However, the total amount of energy never changes; it can only be transferred from one form to another, not created or destroyed. This is known as the “principle of the conservation of energy.”

A Look at History **Albert Einstein, in his theory of relativity, proposed an equation for energy that many have heard of but few understand. He stated that energy equals mass times the speed of light squared or $E = m \times c^2$.**

Engine Efficiency

Engine efficiency is a measurement of the amount of energy put into the engine and the amount of energy available from the engine. It is expressed in a percentage. The formula for determining efficiency is: (output energy \div input energy) \times 100.

Other aspects of the engine are expressed in efficiency. These include mechanical efficiency, volumetric efficiency, and thermal efficiency. They

Figure 8-5 A gasoline engine wastes or loses most of the energy it receives.

are expressed as a ratio of input (actual) to output (maximum or theoretical). Efficiencies are always less than 100%. The difference between the efficiency and 100% is the percentage lost. For example, if 100 units of energy are put into an engine and 28 units were used to power the vehicle, the efficiency is 28%. This means 72% of the energy received was wasted or lost (Figure 8-5).

Kinetic and Potential Energy

When energy is released to do work, it is called **kinetic energy**. Kinetic energy may also be referred to as energy in motion (Figure 8-6). Stored energy is called **potential energy**.

There are many automotive systems that have potential energy and, at times, kinetic energy. The ignition system is a source of high electrical energy.

Figure 8-6 The kinetic energy of a moving vehicle increases exponentially with its speed.

The heart of the ignition system is the ignition coil, which has much potential energy. When it is time to fire a spark plug, that energy is released and becomes kinetic energy as it creates a spark across the gap of a spark plug.

Energy Conversion

Energy conversion occurs when one form of energy is changed to another. Because energy is not always in the desired form, it must be converted to a form that can be used. Some of the most common energy conversions are discussed here.

Chemical to Thermal Energy Chemical energy in gasoline or diesel fuel is converted to thermal energy when the fuel burns in the engine cylinders.

Chemical to Electrical Energy The chemical energy in a battery (Figure 8-7) is converted to electrical energy to power many of the accessories on an automobile.

Figure 8-7 Chemical energy is converted to electrical energy in a battery.

Electrical to Mechanical Energy In an automobile, the battery supplies electrical energy to the starting motor, and this motor converts the electrical energy to mechanical energy to crank the engine.

Thermal to Mechanical Energy The thermal energy that results from the burning of the fuel is converted to mechanical energy, which is used to move the vehicle.

Mechanical to Electrical Energy The generator is driven by the mechanical energy of the engine. The generator converts this energy to electrical energy to power the vehicle's electrical accessories and recharges the battery.

Electrical to Radiant Energy Radiant energy is light energy. Electrical energy is converted to thermal energy to heat up a filament inside a light bulb to illuminate it and release radiant energy.

Kinetic to Mechanical to Electrical Energy Hybrid vehicles have a system, called regenerative braking, that uses the energy of the moving vehicle (kinetic) to rotate a generator. The mechanical energy used to operate the generator is used to provide electrical energy to charge the batteries (Figure 8-8) or power the electric drive motor.

Mass and Weight

Mass is the amount of matter in an object. **Weight** is a force and is measured in pounds or kilograms. Gravitational force gives the mass its weight. As an example, a spacecraft can weigh 500 tons (one million pounds) here on earth where it is affected by the earth's gravitational pull. In outer space, beyond the earth's gravity and atmosphere, the spacecraft is nearly weightless but its mass remains unchanged (Figure 8-9).

Figure 8-8 Regenerative braking captures some of the vehicle's kinetic energy to charge the batteries or power the electric drive motor.

Figure 8-9 The difference in weight of a space shuttle on earth and in space.

Automobile specifications list the weight of a vehicle primarily in two ways. **Gross weight** is the total weight of the vehicle when it is fully loaded with passengers and cargo. **Curb weight** is the weight of the vehicle when it is not loaded with passengers or cargo.

Metric Conversion To convert kilograms into pounds, simply multiply the weight in kilograms by 2.2046. For example, if something weighs 5 kilograms, then $5 \times 2.2046 = 11.023$ pounds. To express the answer in pounds and ounces, convert the 0.023 pound into ounces. Because there are 16 ounces in a pound, multiply 16 by 0.023 ($16 \times 0.023 = 0.368$ ounce). Therefore, 5 kilograms is equal to 11 pounds and 0.368 ounce.

Size

The size of something is related to its mass. An object's size defines how much space it occupies. Size dimensions are typically stated in terms of its length, width, and height. Length is a measurement of how long something is from one end to another. Width is a measurement of how wide something is from one side to another. Obviously height is the distance from something's bottom to its top. All three of these dimensions are measured in inches, feet, yards, and miles in the English system and meters in the metric system.

Sometimes distance measurements are made with a rule that has fractional, rather than decimal,

increments. Most automotive specifications are given decimally; therefore, fractions must be converted into decimals. It is also easier to add and subtract dimensions if they are expressed in decimal form rather than fractions. If you want to find the rolling circumference of a tire and the diameter of the tire is 20 $\frac{3}{8}$ inches, convert the fraction to decimals before going further. The distance around the tire is the circumference and is equal to the diameter multiplied by a constant called pi (π). Pi is equal to approximately 3.14; therefore, the circumference of the tire is equal to the diameter multiplied by 3.14. Convert the 20 $\frac{3}{8}$ inches into a whole number and a decimal. To convert the $\frac{3}{8}$ to a decimal, divide 3 by 8 ($3 \div 8 = 0.375$). Therefore, the diameter of the tire is 20.375 inches. Now multiply the diameter by π ($20.375 \times 3.14 = 63.98$). The circumference of the tire is nearly 64 inches.

Metric Conversion To convert meters into feet, multiply the number of meters by 3.281. To convert feet into inches, multiply the number of feet by 12. For example, to convert 0.01 mm to inches, begin by converting 0.01 mm into meters. Because 1 mm is equal to 0.001 meter, multiply 0.01 by 0.001 ($0.001 \times 0.01 = 0.00001$). Then multiply 0.00001 meter by 3.281 ($0.00001 \times 3.281 = 0.00003281$ foot). Now convert feet into inches by multiplying by 12 ($0.00003281 \times 12 = 0.00039372$ inch).

To do this easier, recognize that 1 mm is equal to 0.03937 inch. Then multiply 0.01 mm by 0.03937 ($0.01 \times 0.03937 = 0.0003937$ inch).

VOLUME

Volume is also a measurement of size and is related to mass and weight. Volume is the amount of space occupied by an object in three dimensions: length, width, and height. For example, a pound of gold and a pound of feathers both have the same weight, but the pound of feathers occupies a much larger volume. In the English system, volume is measured in cubic inches, cubic feet, cubic yards, or gallons. The measurement for volume in the metric system is cubic centimeters or liters (**Figure 8-10**).

The volume of a container is calculated by taking an object's measured length, width, and height and multiplying them. For example, if a box has a length of 2 inches, a width of 3 inches, and a height of 4 inches ($2 \times 3 \times 4 = 24$), its volume equals 24 cubic inches. Different shapes have different formulas for calculating volume but all consider the object's three dimensions.

The volume of an engine's cylinders is expressed as displacement. This size does *not* reflect the exter-

Figure 8-10 A comparison of metric and English units of volume.

Figure 8-11 The bore and stroke of an engine.

nal (length, width, and height) of the engine. Cylinder **displacement** is the maximum volume of a cylinder. A piston's travel from its lowest point (BDC) to its highest point (TDC) within the cylinder is called the stroke of the piston (**Figure 8-11**). A cylinder's bore is the diameter of the cylinder.

Displacement is usually measured in cubic inches, cubic centimeters, or liters. The total displacement of an engine (including all cylinders) is a rough indicator of its power output. Total displacement is the sum of displacements for all cylinders in an engine. Engine cubic inch displacement (CID) may be calculated as follows:

$$CID = \pi \times R^2 \times L \times N$$

where $\pi = 3.1416$

R = the radius of the cylinder or (the diameter, the bore, $\div 2$)

L = length of stroke

N = number of cylinders in the engine

Example: Calculate the CID of a six-cylinder engine with a 3.7 in. bore and 3.4 in. stroke.

$$CID = 3.1416 \times 1.85^2 \times 3.4 \times 6$$

$$CID = 219.66$$

SHOP TALK

Engine displacement can also be calculated by using this formula: $0.7854 \times \text{Bore} \times \text{Bore} \times \text{Stroke} \times \text{Number of cylinders} = \text{Displacement}$

Most of today's engines are listed by their metric displacement. Cubic centimeters and liters are determined by using metric measurements in the displacement formula.

Example: Calculate the metric displacement of a four-cylinder engine with a 78.9 mm stroke and a 100 mm bore. Before you use the formula to find the displacement in cubic centimeters, convert the millimeter measurements to centimeters: 78.9 mm = 7.89 cm and 100 mm = 10 cm.

$$\text{Displacement} = 3.1416 \times 5^2 \times 7.89 \times 4$$

Displacement = 2479 cubic centimeters (cc) or approximately 2.5 liters (L)

Ratios

Often automotive features are expressed as ratios. A ratio expresses the relationship between two things. If something is twice as large as another, there is a ratio of 2:1. Sometimes ratios are used to compare the movement of an object. For example, if a 1-inch movement by something causes something else to move 2 inches, there is a travel ratio of 1:2.

An engine's **compression ratio** expresses how much the air and fuel mixture is compressed as a cylinder's piston moves from the bottom (BDC) to the top (TDC) of the cylinder. The compression ratio is defined as the ratio of the volume in the cylinder above the piston when the piston is at BDC to the volume in the cylinder is at TDC (**Figure 8-12**). The formula for calculating the compression ratio is as follows:

$$\frac{\text{volume above the piston at BDC} \div \text{volume above the piston at TDC}}{\text{or}}$$

$$\frac{\text{total cylinder volume} \div \text{total combustion chamber volume}}$$

In many engines, the top of the piston is at the top of the cylinder block during TDC. The combustion chamber is the cavity in the cylinder head above the piston. This may be modified slightly by the shape of the top of the piston. The volume of the combustion chamber must be added to each volume in the formula in order to get an accurate calculation of compression ratio.

Figure 8-12 An engine's compression ratio indicates the amount the air and fuel mixture is compressed during the compression stroke of a piston.

Example: Calculate the compression ratio if the total piston displacement is 45 cubic inches and the combustion chamber volume is 5.5 cubic inches.

$$45 \div 5.5 = 9.1$$

Therefore, the compression ratio is 9.1 to 1 or 9.1:1.

Proportions

Ratios are also used to express the correct mixture for something. For example, engine coolant should typically be mixed with 50% coolant and 50% water when the cooling system is refilled (**Figure 8-13**). This is a 1:1 ratio. This ratio allows for maximum hot and cold protection.

Consider a cooling system that has a capacity of 9.5 liters. Because most coolant is sold in gallon containers, to determine the amount of coolant that should be put in the system, first convert the liter

Figure 8-13 The relationship of the percentage of antifreeze to the freezing and boiling points of the engine's coolant.

capacity to gallons. Because 1 gallon equals 3.7854 liters, divide 9.5 liters by 3.7854 ($9.5 \div 3.7854 = 2.5097$). Therefore, the total capacity of the cooling system is a little more than 2.5 gallons. To determine how much coolant or antifreeze to put in the system, divide the total capacity by 2 ($2.5 \div 2 = 1.25$). Therefore, the correct mixture is $1\frac{1}{4}$ gallons of coolant mixed with $1\frac{1}{4}$ gallons of water.

FORCE

A **force** is a push or pull and can be large or small. Force can be applied by direct contact or from a distance. Gravity and electromagnetism are examples of forces that are applied from a distance. Forces can be applied from any direction and with any intensity. For example, if a pulling force is twice that of the pushing force, the object will be pulled at one-half of the pulling force. When two or more forces are applied to an object, the combined force is called the resultant. The resultant is the sum of the amount and direction of the forces. For example, when a mass is suspended by two lengths of wire, each wire will carry half the weight of the mass. If the attachment of the wires is moved so they are now at an angle to the mass, the wires will carry more force. They now carry the force of the mass plus the force that pulls against the other wire.

Automotive Forces

When a vehicle is sitting still, gravity exerts a downward force on the vehicle. The ground exerts an equal and opposite upward force and supports the vehicle. When the engine is running and its power is transferred to the drive wheels, the wheels exert a force against the ground in a horizontal direction. This causes the vehicle to move but it is opposed by the mass of the vehicle (**Figure 8-14**). To move the vehicle faster, the force supplied by the wheels must increase beyond the opposing forces. As the vehicle

Figure 8-14 The amount of energy required to move a vehicle depends on its mass.

does move faster, it pushes against the air as it travels. This becomes a growing opposing force, and the force at the drive wheels must overcome that force in order for the vehicle to increase speed. After the vehicle has achieved the desired speed, no additional force is required at the drive wheels.

Force—Balanced and Unbalanced When the applied forces are balanced and there is no overall resultant force, the object is in **equilibrium**. An object sitting on a solid flat surface is in equilibrium. If the surface is set at a slight angle, the forces will cause the object to slowly slide down the surface. If the surface is at a severe angle, the downward force will cause the object to quickly slide down the slope. In both cases, the surface is still supplying the force needed to support the object but the pull of gravity is greater and the resultant force causes the object to slide down.

Turning Forces Forces can cause rotation as well as straight line motion. A force acting on an object that is free to rotate will have a turning effect, or turning force. This force is equal to the force multiplied by the distance of the force from the turning point around which it acts.

Forces on Tires and Wheels

If you roll a cone-shaped object on a smooth surface, the cone will not roll in a straight line. Rather it will move in the direction of the cone's tilt (**Figure 8-15**). Riding a bicycle is an example of this. To turn left, it is easier to tilt the bicycle to the left. A tilted, rolling wheel tends to move in the direction of the tilt. Similarly, if a vehicle's tire and wheel are tilted, the tire and

Figure 8-15 A tire at an angle will roll in the same way as a cone would.

wheel will tend to move in the direction of the tilt. This is a principle considered during wheel alignment.

While riding a bicycle, your weight is projected through the bicycle's front fork to the road surface. The centerline of the front fork is tilted rearward in relation to the vertical centerline of the wheel. When the handle bars are turned, the tire pivots on the wheel's vertical centerline. Because the tire's pivot point is behind where your weight is projected against the surface of the road, the front wheel tends to return to the straight-ahead position after a turn. The wheel also tends to remain in the straight-ahead position as the bicycle is driven. This principle of resultant forces is the basis for precise wheel alignment.

Centrifugal/Centripetal Forces

When an object moves in a circle, its direction is continuously changing. All directional changes require a force. The forces required to maintain a circular motion are called **centripetal** and **centrifugal forces**. The required forces depend on the size of the circle and the object's mass and speed.

Centripetal force tends to pull the object toward the center of the circle. Centrifugal force tends to push the object away from the center. The centripetal force that keeps an object whirling around on the end of a string is caused by **tension** in the string. If the string breaks, there is no longer string tension and the object will fly off in a straight line because of the centrifugal force on it. Gravity is the centripetal force that keeps the planets orbiting around the sun. Without this centripetal force, the earth would move in a straight line through space.

Wheel and Tire Balance

When the weight of a wheel and tire assembly is distributed equally around the center of wheel rotation, the wheel and tire has proper static balance. Being statically balanced, the wheel and tire assembly will not tend to rotate by itself, regardless of the wheel position. If the weight is not distributed equally, the wheel and tire assembly is statically unbalanced. As the wheel and tire rotate, centrifugal force acts on this static unbalance and causes the wheel to "tramp" or "hop" (**Figure 8-16**).

Dynamic balance exists when the weight thrown to the sides of a rotating tire and wheel assembly are equal (**Figure 8-17**). To illustrate this, assume we have a bar with a ball attached by string to both ends of the bar. If we rotate the bar, the balls will turn with the bar and the centripetal and centrifugal forces will keep the balls in an orbit around the rotating bar. If the two balls weigh the same and are at an equal

Figure 8-16 Wheel tramp is the result of a tire and wheel assembly being statically unbalanced.

Figure 8-17 Dynamic imbalance causes wheel shimmy.

distance from the bar, the bar will rotate smoothly. However, if one of the balls is heavier, the bar will wobble as it rotates. The greater the difference in weight, the greater the wobble. The wobble can eventually destroy the mechanism used to rotate the bar.

Now if we add some weight to the end of the bar that has the lighter ball, the weights and forces can be equalized and the wobble removed. This is basically how we dynamically balance a wheel and tire assembly (**Figure 8-18**).

When we think of all the parts of an automobile that rotate, it is easy to see why proper balance is important. Improper balance can cause premature wear or destruction of parts.

Pressure

Pressure is a force applied against an object and is measured in units of force per unit of surface area (pounds per square inch or kilograms per square centimeter). Mathematically, pressure is equal to the applied force divided by the area over which the force acts. Consider two 10-pound weights sitting on a table; one occupies an area of 1 square inch and the

Figure 8-18 Adding a weight to counteract with the heavy spot of a tire and wheel assembly.

other an area of 4 square inches. The pressure exerted by the first weight would be 10 pounds per 1 square inch or 10 psi. The other weight, although it weighs the same, will exert only 2.5 psi (10 pounds per 4 square inches = $10 \div 4 = 2.5$). This shows that a force acting over a large area will exert less **pressure** than the same force acting over a small area.

Because pressure is a force, all principles of force apply to pressure. If more than one pressure is applied to an object, the object will respond to the resultant force. Also, all matter (liquids, gases, and solids) tend to move from an area of high pressure to an area of low pressure.

TIME

The word **time** is used to mean many things. For this discussion, time is defined as a measurement of the duration of something that has happened, is happening, or will happen. Time is measured by the increments of a clock: seconds, minutes, and hours. Often an automotive technician is concerned with how long something occurs, such as the length of time a spark plug fires to cause combustion. This time, called spark duration, is typically about 3 milliseconds (0.003 second) and is measured with a lab scope because it would be very difficult to measure that short of a time with a clock.

Technicians also monitor how many times a cycle is repeated within a period of time, such as a minute. A tachometer, which measures engine revolutions per minute, is an often used diagnostic tool.

MOTION

When the forces on an object do not cancel each other out, they will change the object's speed or direction of motion, or both. The greater the object's mass, the greater the force must be to change its motion. This

resistance to change is called **inertia**. Inertia is the tendency of an object at rest to remain at rest or the tendency of an object in motion to stay in motion in one direction. The inertia of an object at rest is called static inertia, whereas the inertia of an object in motion is called dynamic inertia. Inertia exists in liquids, solids, and gases. When you push and move a parked vehicle, you overcome the static inertia of the vehicle. If you catch a ball in motion, you overcome the dynamic inertia of the ball.

When a force overcomes static inertia and moves an object, the object gains momentum. **Momentum** is the product of an object's weight and speed. Momentum is a type of mechanical energy. An object loses momentum if another force overcomes the dynamic inertia of the moving object.

Rates

Speed is the distance an object travels in a set amount of time. It is calculated by dividing the distance traveled by the time it took to travel that distance. We refer to the speed of a vehicle in miles per hour (mph) or kilometers per hour (km/h). **Velocity** is the speed of an object in a particular direction. **Acceleration** is the rate of increase in speed. Acceleration is calculated by dividing the change in speed by the time it took for that change. **Deceleration** is the reverse of acceleration; it is the rate of a decrease in speed.

Newton's Laws of Motion

How forces change an object's motion was first explained by Sir Isaac Newton in what is known as Newton's laws. Newton's first law of motion is called the law of inertia. It states that an object at rest tends to remain at rest and an object in motion tends to remain in motion, unless some force acts on it. When a car is parked on a level street, it remains stationary unless it is driven or pushed.

Newton's second law states that when a force acts on an object, the motion of the object will change. This change is equal to the size of the force divided by the object's mass. Trucks have a greater mass than cars. Because a large mass requires a larger force to produce a given acceleration, a truck needs a larger engine than a car.

Newton's third law says that for every action there is an equal and opposite reaction. A practical application of this occurs when the wheel strikes a bump in the road. This action drives the wheel and suspension upward with a certain force, and a specific amount of energy is stored in the spring. After this, the spring forces the wheel and suspension downward with a force equal to the initial upward force caused by the bump.

Friction

Friction is a force that slows or prevents the motion of two objects or surfaces that touch. Friction may occur in solids, liquids, and gases. It is the joining or bonding of the atoms at each of the surfaces that causes the friction. When you attempt to pull an object across a surface, the object will not move until these bonds are overcome. Smooth surfaces produce little friction; therefore, only a small amount of force is needed to break the bonds of the atoms. Rougher surfaces produce a larger friction force because there are stronger bonds between the two surfaces (**Figure 8-19**). To move an object over a rough surface, such as sandpaper, a great amount of force is required.

Friction is put to good use in disc brakes (**Figure 8-20**). The friction between the brake disc and

Figure 8-19 Sliding ice across a surface produces less friction than sliding a rougher material, such as iron, across a surface.

Figure 8-20 As pressure is applied to the friction pads, the pads attempt to stop the rotor to which the tire and wheel are attached.

pad slows the rotation of the wheel, reducing the vehicle's speed. In doing so, it converts the kinetic energy of the vehicle into heat.

Lubrication Friction can be reduced in two main ways: by lubrication or by the use of rollers. The presence of oil or another fluid between two surfaces keeps the surfaces apart. Because fluids (liquids and gases) flow, they allow movement between surfaces. The fluid keeps the surfaces apart, allowing them to move smoothly past one another (**Figure 8-21**).

Rollers Rollers placed between two surfaces also keep the surfaces apart. An object placed on rollers will move smoothly if pushed or pulled. Instead of sliding against one another, the surfaces produce turning forces, which cause each roller to spin. This leaves very little friction to oppose motion. Bearings are a type of roller used to reduce the friction between moving parts such as a wheel and its axle (**Figure 8-22**). As the wheel turns on the axle, the balls in the bearing roll around inside the bearing, drastically reducing the friction between the wheel and axle.

Figure 8-21 Oil separates the rotating shaft from the stationary bearing.

Figure 8-22 An assortment of tapered roller bearings and their races.

Air Resistance

When a vehicle is driven, resistance occurs between the air and the vehicle's body. This resistance or friction opposes the momentum, or mechanical energy, of the moving vehicle. The mechanical energy from the engine must overcome the vehicle's inertia and the friction of the air striking the vehicle. The faster an object moves, the greater the air resistance.

Body design, obviously, affects the amount of friction developed by the air striking the vehicle. The total resistance to motion caused by friction between a moving vehicle and the air is referred to as coefficient of drag (Cd). At 45 miles per hour (72 kilometers per hour), half of the engine's mechanical energy can be used to overcome air resistance. Therefore, reducing a vehicle's Cd is a very effective way to improve fuel economy. Cd may also be called aerodynamic drag.

Aerodynamics is the study of the effects of air on a moving object (Figure 8-23). The basics of this science are fairly easy to understand. The larger the area facing the moving air is, the more the air will tend to hold back or resist forward motion.

Needless to say, the less air a vehicle pushes out of its way, the less power it needs to move at a given speed. If engineers want a vehicle that uses less fuel and emits fewer pollutants, they do whatever it takes to make the engine work less hard. Aerodynamics is one of those things.

Most aerodynamic design work is done initially on a computer; the design is then checked and modified by placing the vehicle in a wind tunnel (Figure 8-24). A wind tunnel is a carefully constructed facility with a large fan at one end. Inside the tunnel, the movement of air over, under, and around the vehicle is studied.

Ideally, the air moved by the vehicle will follow the contours of the vehicle. This prevents the air from

Figure 8-24 This wind tunnel can generate winds as high as 150 miles per hour. *Courtesy of Chrysler LLC*

doing funny things as it is pushed away. If the air that moves under the vehicle has a place to push up, the vehicle will tend to lift. This creates poor handling, a situation that can be very unsafe. Air can also be trapped under the vehicle, which increases the vehicle's air drag. If air moving over the top pushes against the vehicle, there is an increase in air drag. To help direct the air and make it usable, air dams and spoilers or wings are used.

WORK

When a force moves a mass a specific distance, **work** is done. When work is accomplished, a mass may be lifted or pushed against a resistance or opposing force (Figure 8-25). Work is equal to the applied force multiplied by the distance the object moved

Figure 8-23 The movement of air as it goes over this car. *Courtesy of Chrysler LLC*

Figure 8-25 When work is performed, a mass is moved a certain distance.

Figure 8-26 1,000 foot-pounds of work.

(force \times distance = work) and is measured in foot-pounds (**Figure 8-26**), watts, or Newton-meters. For example, if a force moves a 3,000-pound car 50 feet, 150,000 foot-pounds of work was done.

During work, a force acts on an object to start, stop, or change its direction. It is possible to apply a force and not move the object. For example, you may push with all your strength on a car stuck in a ditch and not move it. This means no work was done. Work is only accomplished when an object is started, stopped, or redirected by a force.

Simple Machines

A machine is any device used to transmit a force and, in doing so, changes the amount of force and/or its direction. A common example of a simple machine that does both is a valve rocker arm. One end of a rocker arm is pushed up by the action of the engine's camshaft. When this happens, the other end of the rocker arm pushes down on a valve to open it. A rocker arm is also designed to change the size of the force applied to it. Rocker arms provide more movement on the valve side or output than the input side. This is referred to as the rocker arm's ratio. If a rocker arm has a ratio of 1.5:1, one end of it will move 1.5 times more than the other (**Figure 8-27**). For

Figure 8-27 A rocker arm with a ratio of 1:1.5.

Figure 8-28 It takes less energy to pull a mass up an inclined plane than would be required to lift the mass vertically.

example, if the camshaft causes one end of the rocker arm to move $\frac{1}{2}$ inch, the other end will move $\frac{3}{4}$ of an inch.

The force applied to a machine is called the effort, while the force it overcomes is called the **load**. The effort is often smaller than the load, because a small effort can overcome a heavy load if the effort is moved a larger distance. The machine is then said to give a mechanical advantage. Although the effort will be smaller when using a machine, the amount of work done, or energy used, will be equal to or greater than that without the machine.

Inclined Plane The force required to drag an object up a slope (**Figure 8-28**) is less than that required to lift it vertically. However, the overall distance moved by the object is greater when pulled up the slope than if it were lifted vertically. A screw is an inclined plane wrapped around a shaft. The force that turns the screw is converted to a larger one, which moves a shorter distance and drives the screw in.

Pulleys A **pulley** is a wheel with a grooved rim in which a rope, belt, or chain runs to move something by pulling on the other end of the rope, belt, or chain. A simple pulley changes the direction of a force but not its size. Also, the distance the force moves does not change. By using several pulleys connected together as in a block and tackle, the size of the force can be changed too, so that a heavy load can be lifted using a small force. With a double pulley, the required applied force to move an object can be reduced by one-half but the distance the force must be moved is doubled. A quadruple pulley can reduce the force by four times but the distance will be increased by four times. Pulleys of different sizes can change the required applied force as well as the speed or distance the pulley needs to travel to accomplish work (**Figure 8-29**).

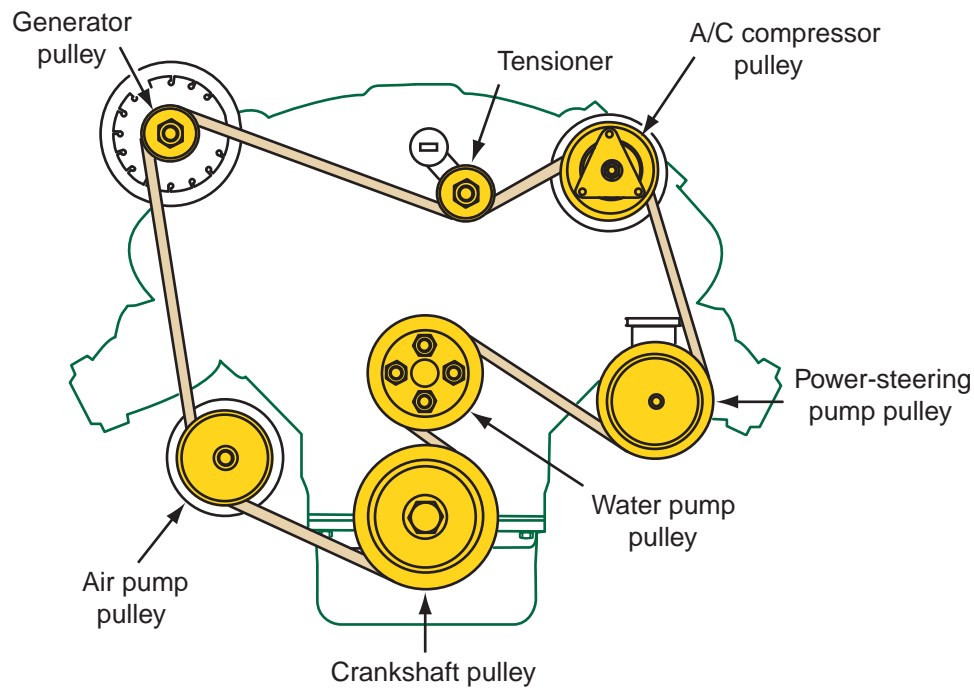

Figure 8-29 Accessories are driven by a common drive belt but they rotate at different speeds because of the differences in pulley size.

Levers A **lever** is a device made up of a bar moving on a fixed pivot point called the fulcrum. A lever uses a force applied at one point to move a mass on the other end of the bar. Levers are divided into classes. In a class one lever, the fulcrum is between the effort and the load (**Figure 8-30**). The load is larger than the effort, but it moves a smaller distance. A pair of pliers is an example of a class one lever. In a class two lever, the load is between the fulcrum and the effort. Here again, the load is greater than the effort and moves through a smaller distance (**Figure 8-31**). In a class three lever, the effort is between the fulcrum and the load. In this case, the load is less than the effort but it moves through a greater distance.

Gears A **gear** is a toothed wheel that becomes a machine when it is meshed with another gear. The action of one gear is the same as a rotating lever and moves the other gear with it. Based on the size of the gears, the amount of force applied from one gear to

the other can be changed. Keep in mind that this does not change the amount of work performed by the gears because the change in force is accompanied by a change in the distance of travel (**Figure 8-32**). The relationship of force and distance is inverse. Gear ratios express the mathematical relationship (diameter and number of teeth) of one gear to another.

Wheels and Axles The most obvious application of a wheel and axle is a vehicle's tires and wheels. These revolve around an axle and limit the amount of area that contacts the road. Wheels function as rollers to reduce the friction between a vehicle and the road. Basically, the larger the wheel, the less force is required to turn it. However, the wheel moves farther as it gets larger. An example of this is a steering wheel. A steering wheel that is twice the size of another will require one-half the force to turn it but will also require twice the distance to accomplish the same work.

Figure 8-30 A mechanical advantage can be gained with a class one lever.

Figure 8-31 A brake pedal assembly is an example of a class two lever.

Figure 8-32 When a small gear drives a larger gear, the larger gear turns with more force but travels less; therefore, the amount of work stays the same.

Torque

Torque is a force that tends to rotate or turn things and is measured by the force applied and the distance traveled. The technically correct unit of measurement for torque is pounds per foot (lb-ft.). However, it is rather common to see torque stated as foot-pounds (ft.-lb). In the metric, or SI, system, torque is stated in Newton-meters (N-m) or kilogram-meters (kg-m).

An engine creates torque and uses it to rotate the crankshaft. The combustion of gasoline and air creates pressure against the top of a piston. That pressure creates a force on the piston and pushes it down.

Figure 8-33 The amount of torque applied to a wrench is changed by the length of the wrench.

The force is transmitted from the piston to the connecting rod and from the connecting rod to the crankshaft. The engine's crankshaft rotates with a torque that is sent through the drivetrain to turn the drive wheels of the vehicle.

Torque is force times leverage, the distance from a pivot point to an applied force. Torque is generated any time a wrench is turned with force. If the wrench is a foot long, and you put 20 pounds of force on it, 20 pounds per foot are being generated. To generate the same amount of torque while exerting only 10 pounds of force, the wrench needs to be 2 feet long (**Figure 8-33**). To have torque, it is not necessary to have movement. When you pull a wrench to tighten a bolt, you supply torque to the bolt. If you pull on a wrench to check the torque on a bolt and the bolt torque is sufficient, torque is applied to the bolt but no movement occurs. If the bolt turns during torque application, work is done. When a bolt does not rotate during torque application, no work is accomplished.

Torque Multiplication

When gears with different numbers of teeth mesh, each rotates at a different speed and force. Torque is calculated by multiplying the force by the distance from the center of the shaft to the point where the force is exerted.

The distance from the center of a circle to its outside edge is its radius. On a gear, the radius is the distance from the center of the gear to the point on its teeth where force is applied.

If a tooth on the driving gear is pushing against a tooth on the driven gear with a force of 25 pounds and the force is applied at a distance of 1 foot (the radius of the driving gear), a torque of 25 ft.-lb is applied to the driven gear. The 25 pounds of force from the teeth of the smaller (driving) gear is applied to the teeth of

the larger (driven) gear. If that same force were applied at a distance of 2 feet from the center, the torque on the shaft of the driven gear would be 50 ft.-lb (see Figure 8-32). The same force is acting at twice the distance from the shaft center.

The amount of torque that can be applied from a power source is proportional to the distance from the center at which it is applied. If a fulcrum or pivot point is placed closer to the object being moved, more torque is available to move the object, but the lever must move farther than if the fulcrum were farther away from the object. The same principle is used for gears in mesh: A small gear will drive a large gear more slowly but with greater torque.

A drivetrain consisting of a driving gear with eleven teeth and a radius of 1 inch and a driven gear with forty-four teeth and a radius of 4 inches will have a torque multiplication factor of 4 and a speed reduction of $\frac{1}{4}$. Thus, the larger gear will turn with four times the torque but one-fourth the speed (Figure 8-34). The radii between the teeth of a gear act as levers.

Gear ratios express the mathematical relationship of one gear to another. Gear ratios can vary by changing the diameter and number of teeth of the gears in mesh. A gear ratio also expresses the amount of torque multiplication between two gears. The ratio is obtained by dividing the diameter or number of teeth of the driven gear by the diameter or teeth of the drive gear. If the smaller driving gear had eleven teeth and the larger gear had forty-four teeth, the ratio is 4:1.

Power

Power is a measurement of the rate, or speed, at which work is done. The metric unit for power is the watt. A watt is equal to one Newton-meter per sec-

Figure 8-34 The driving gear must rotate four times to rotate the driven gear once.

ond. Power is a unit of speed combined with a unit of force. For example, if you were pushing something with a force of 1 N and it moved at 1 meter per second, the power output would be 1 watt.

In electrical terms, 1 watt is equal to the amount of electrical power produced by a current of 1 ampere across a potential difference of 1 volt. This is expressed as Power (P) = Voltage (E) \times Current (I) or $P = E \times I$.

Horsepower

Horsepower is the rate at which torque is produced. James Watt is credited with being the first person to calculate horsepower and power. He measured the amount of work a horse could do within a specific time. A horse could move 330 pounds 100 feet in 1 minute (Figure 8-35). Therefore, he determined that one horse could do 33,000 ft.-lb of work in 1 minute. Thus, 1 horsepower is equal to 33,000 ft.-lb per minute, or 550 ft.-lb per second. Two horsepower could do this same amount of work in $\frac{1}{2}$ minute. If you push a 3,000-pound (1,360-kilogram) car for 11 feet (3.3 meters) in $\frac{1}{4}$ minute, you produce 4 horsepower.

An engine producing 300 ft.-lb of torque at 4,000 rpm produces 228 horsepower at 4,000 rpm. This is based on the fact that horsepower is equal to torque multiplied by engine speed, and that quantity is divided by 5252 ([torque \times engine speed] \div 5252 = horsepower). The constant, 5252, is used to convert the rpm into revolutions per second.

SHOP TALK

Manufacturers are now rating their engines' outputs in watts. One horsepower is equal to approximately 746 watts. Therefore, a 228 hp engine is rated at 170,088 watts or about 170 kW.

Figure 8-35 This is how James Watt defined 1 horsepower.

WAVES AND OSCILLATIONS

An **oscillation** is the back-and-forth movement of an object between two points. When that motion travels through matter or space, it becomes a **wave**. A mass suspended by a spring, for example, is acted on by two forces: gravity and the tension in the spring. At the point of equilibrium, the resultant of these forces is zero. When the mass is given a downward push, the tension of the spring exceeds the weight of the mass. The resultant upward force accelerates the mass back up toward its original position and its momentum carries it farther upward. When the weight exceeds the spring's tension, the mass moves down again and the oscillation repeats itself until the mass is at equilibrium. As the mass oscillates toward the equilibrium position, the size of the oscillation decreases. As the mass oscillates, the air around it moves and becomes an air wave.

Vibrations

When an object oscillates, it vibrates (**Figure 8-36**). To prevent the vibration of one object from causing a vibration in other objects, the oscillating mass must be isolated from other objects. This is often a difficult task. For example, all engines vibrate as they run. To reduce the transfer of engine vibrations to the rest of the vehicle, the engine is held by special mounts. The materials used in the mounts must keep the engine in place and must be elastic enough to absorb the engine's vibrations (**Figure 8-37**). If the engine was mounted solidly, the vibrations would be felt throughout the vehicle.

Vibration control is also important for the reliability of components. If the vibrations are not controlled, the object could shake itself to destruction. Vibration control is the best justification for always mounting parts in the way they were designed to be mounted.

Unwanted and uncontrolled vibrations typically result from one component vibrating at a different

Figure 8-36 Vibrations happen in cycles; notice how the yardstick moves up and down in cycles.

Figure 8-37 An engine mount holds the engine in place and isolates engine vibrations from the rest of the vehicle.

frequency than another part. When two waves or vibrations meet, they add up or interfere. This is called the principle of superposition and is common to all waves. Making unwanted vibrations tolerable can be done by canceling them with equal and opposite vibrations. This approach to vibration reduction is best illustrated by the use of balance shafts in an engine. These shafts are designed to counter the vibrations caused by the rotation of the engine's crankshaft and pistons (**Figure 8-38**). The balance shaft spins and creates an equal but opposite vibration to cancel the vibrations of the crankshaft.

Figure 8-38 Balance shafts are driven by the crankshaft and work to counter crankshaft pulses and vibrations by acting with an equal force but in the opposite direction. *Courtesy of BMW of North America, LLC*

Figure 8-39 Frequency is a statement of how many cycles occur in a second.

How many times the vibration occurs in 1 second is called **frequency**. Frequency (**Figure 8-39**) is most often expressed in **hertz** (Hz). One hertz is equal to one cycle per second. The name is in honor of Heinrich Hertz, an early German investigator of radio wave transmission. The **amplitude** of a vibration is its intensity or strength (**Figure 8-40**). The velocity of a vibration is the result of its amplitude and its frequency. All materials have a unique resonant or natural vibration frequency.

Sound

Vibration results in the phenomenon of sound. In air, the vibrations that cause sound are transmitted as a wave between air molecules; many other substances transmit sound in a similar way. A vibrating object causes pressure variations in the surrounding air. Areas of high and low pressure, known as compressions and rarefactions, move through the air as sound waves. Compression makes the sound waves denser, whereas rarefaction makes them less dense. The distance between each compression of a sound wave is called its **wavelength**. Sound waves with a short wavelength have a high frequency and a high-pitched sound.

When the rapid variations in pressure occur between about 20 Hz and 20 kHz, sound is audible. Audible sound is the sensation (as detected by the

ear) of very small rapid changes in the air pressure above and below atmospheric pressure.

Certain terms are used to describe sound:

- The pitch of a sound is based on its frequency. The greater the frequency, the higher the pitch.
- A decibel is a numerical expression of the loudness of a sound.
- Intensity is amount of energy in a sound wave.
- An overtone is an additional tone that is heard because of the air waves of the original tone.
- Harmonics result from the presence of two or more tones at the same time.
- Resonance is produced when the natural vibration of a mass is greatly increased by vibrations at the same or nearly the same frequency of another source or mass. A cavity has certain resonant frequencies. These frequencies depend on the shape and size of the cavity and the velocity of sound within the cavity.

During diagnostics, you often need to listen to the sound of something. You will be paying attention to the type of sound and its intensity and frequency. The tone of the sound usually indicates the type of material that is causing the noise. If there is high pitch, you know that the source of the sound is something that is vibrating quickly. This means the source is less rigid than something that vibrates with a low pitch. Although pitch is dependent on the sound's frequency, the frequency itself can identify the possible sources of the sound. For example, if a sound from an engine increases with an increase in engine speed, you know that the source of the sound must be something that is moving faster as a result of the increase in engine speed. If the frequency of the sound appears to be at one-half the speed of the engine, you know that the source of the sound is something that is rotating at that speed, such as the camshaft.

Figure 8-40 Amplitude is a measurement of a vibration's intensity.

Figure 8-41 A variety of speakers. Courtesy of Robert Bosch GmbH, www.bosch-presse.de

Speakers A speaker (**Figure 8-41**) converts electrical energy into sound energy or waves. A constantly changing electrical signal is fed to the coil of a speaker, which lies within the magnetic field of a permanent magnet. The signal in the coil causes it to behave like an electromagnet, making it push against the field of the permanent magnet. The speaker cone is then pushed in and out by the coil in time with the electrical signal. As the cone moves forward, the air immediately in front of it is compressed, causing a slight increase in air pressure; it then moves back past its rest position and causes a reduction in the air pressure (rarefaction). This process continues so that a wave of alternating high and low pressure is radiated away from the speaker cone at the speed of sound. These changes in air pressure are actually sound. The

sound from a speaker may be amplified by the space or cavity that surrounds the speaker cone. The room or area in which the speaker sits also works to amplify the sound.

Noise

Noise is any unwanted signal or sound. It can be random or periodic. To identify the source of a noise, it is important to remember that sound or noise is a vibration and the vibration may be traveling through other components. Therefore, the source of the noise is not always where it may appear (**Figure 8-42**).

Three approaches can be used to prevent or reduce noise. The most effective way is to intervene at the design stage to make a noisy component produce less noise. A relatively new technique of noise reduction is antinoise or active noise control. This involves producing a sound that is similar to, but out of phase with, the noise. This effectively cancels the original noise. More obvious methods of noise reduction, or passive noise control, involve the use of filters, insulation, and noise barriers.

A filter is an electrical circuit that allows signals in certain frequency ranges to pass through and blocks all other frequencies. Sound insulation prevents sound from traveling from one place to another. Heavy materials like concrete are the most effective materials for sound insulation. Sound insulation or deadening materials are placed strategically throughout a modern automobile. Some sound deadening materials actually absorb sounds. These materials are able to vibrate without creating sound.

Figure 8-42 A vibration and/or noise will easily move through components so that it appears that the responder (in this case, the steering wheel) is the cause of the noise or vibration.

LIGHT

Light is a form of electromagnetic radiation. In free space, it travels in a straight line at 300 million meters per second. When a beam of light meets an object, a proportion of the rays may be reflected. Some light may also be absorbed, and some transmitted. Without reflection, we would only be able to see objects that give out their own light. Light always reflects from a surface at the same angle at which it strikes. Therefore, parallel rays of light reflecting off a very flat surface will remain parallel. A beam of light reflecting from an irregular surface will scatter in all directions. Light that passes through an object is bent or refracted. The angle of refraction depends on the angle at which the light meets the object and the material it passes through. Lenses and mirrors can cause light rays to diverge or converge. When light rays converge, they can reach a point of focus.

These principles are the basis for fiber-optic lighting. With fiber optics, the light from a single lamp moves through one or more fiber cables to illuminate a point away from the source lamp. The fiber cables are designed to allow the light to travel without losing intensity and the light can be delivered to many locations at the same time.

Photo Cells

Radiation is produced in the sun's core during its nuclear reactions and is the source of most of the earth's energy. A transfer of energy, from electromagnetic radiation to electrical energy, takes place in a photovoltaic (photo) cell, or solar cell. When no light falls on it, it can supply no electricity.

LIQUIDS

A fluid is something that does not have a definite shape; therefore, liquids and gases are fluids. A characteristic of all fluids is that they will conform to the shape of their container. A major difference between a gas and a liquid is that a gas will always fill a sealed container, whereas a liquid may not. A gas will also readily expand or compress according to the pressure exerted on it. Liquids are basically incompressible, which gives them the ability to transmit force (**Figure 8-43**). Liquids also always seek a common level. A liquid may also change to a gas in response to temperature increases.

Liquids exert pressure on immersed objects, resulting in an upward resultant force called upthrust. The upthrust is equal to the weight of the liquid displaced by the immersed object. If the upthrust on an object is greater than the weight of the object, then the object will float. Large ships float because they

Figure 8-43 Gases compress, whereas liquids do not.

displace huge amounts of water, producing a large upthrust.

Laws of Hydraulics

Hydraulics is the study of liquids in motion. Liquids will predictably respond to pressures put on them. This allows hydraulics to do work. A simple hydraulic system has liquid, a pump, lines to carry the liquid, control valves, and an output device. The liquid must be available from a continuous source, such as an oil pan or sump. A pump is used to move the liquid through the system. The lines that carry the liquid may be pipes, hoses, or a network of internal bores or passages in a housing. Control valves regulate hydraulic pressure and direct the flow of the liquid. The output device is the unit that uses the pressurized liquid to do work.

Over 300 years ago a French scientist, Blaise Pascal, determined that if you had a liquid-filled container with only one opening and applied force to the liquid through that opening, the force would be evenly distributed throughout the liquid. This explains how pressurized liquid is used to operate and control systems, such as the brake system and automatic transmissions.

Pascal constructed the first known hydraulic device, which consisted of two sealed containers connected by a tube. The cylinders' pistons are sealed against the walls of each cylinder to prevent the liquid from leaking out and to prevent air from entering into the cylinder. When the piston in the first cylinder has a force applied to it, the pressure moves everywhere within the system. The force is transmitted through

Figure 8-44 In a hydraulic circuit, pressure is transferred equally throughout the system.

Figure 8-45 The force available to do work can be increased by increasing the size of the piston doing the work.

the connecting tube to the second cylinder. The pressurized fluid in the second cylinder exerts force on the bottom of the second piston, moving it upward and lifting the load on the top of it (**Figure 8-44**). By using this device, Pascal found he could increase the force available to do work (**Figure 8-45**), just as could be done with levers or gears.

Pascal determined that force applied to liquid creates pressure, or the transmission of the force through the liquid. These experiments revealed two important aspects of a liquid when it is confined and put under pressure. The pressure applied to it is transmitted equally in all directions and this pressure acts with equal force at every point in the container. If a liquid is confined and a force applied, pressure is produced. In order to pressurize a liquid, the liquid must be in a sealed container. Any leak in the container will decrease the pressure.

Mechanical Advantage with Hydraulics

Hydraulics are used to do work in the same way as a lever or gear. These systems transmit energy. Because energy cannot be created or destroyed, these systems only redirect energy to perform work. They do not

Figure 8-46 A pressure applied to a liquid is transmitted equally and acts with equal force at every point within the hydraulic circuit.

create more energy. If a hydraulic pump provides 100 psi, there will be 100 pounds of pressure on every square inch of the system (**Figure 8-46**). If the system included a piston with an area of 50 square inches, each square inch receives 100 pounds of pressure. This means there will be 5,000 pounds of force applied to that piston (**Figure 8-47**). The use of the larger piston gives the system a **mechanical advantage** as it increases the force available to do work. The multiplication of force through a hydraulic system is directly proportional to the difference in the piston sizes throughout the system.

By changing the size of the pistons in a hydraulic system, force is multiplied, and as a result, low amounts of force can be used to move heavy objects. The mechanical advantage of a hydraulic system can be increased further by the use of levers to increase the force applied to a piston.

Although the force available to do work is increased by using a larger piston in one cylinder, the

Figure 8-47 Hydraulic systems can provide an increase in force (mechanical advantage), but the output's travel will decrease proportionally.

total movement of the larger piston is less than that of the smaller one. A hydraulic system with two cylinders, one with a 1-inch piston and the other with a 2-inch, will double the force at the second piston. However, the total movement of the larger piston will be half the distance of the smaller one.

The use of hydraulics to gain a mechanical advantage is similar to the use of levers or gears. Hydraulics is preferred when the size and shape of the system is of concern. In hydraulics, the force applied to one piston will transmit through the fluid and the opposite piston will have the same force on it. The distance between the two pistons in a hydraulic system does not affect the force in a static system. Therefore, the force applied to one piston can be transmitted without change to another piston located somewhere else.

A hydraulic system responds to the pressure or force applied to it. The mere presence of different-sized pistons does not always result in fluid power. Either the pressure applied to the pistons or the size of the pistons must be different to cause fluid power. If an equal amount of pressure is exerted onto the pistons in a system and the pistons are the same size, neither piston will move, and the system is balanced or is at equilibrium. The pressure in a balanced hydraulic system is called **static pressure** because there is no fluid motion.

When an unequal amount of pressure is exerted on the pistons, the piston with the least amount of pressure on it will move in response to the difference between the two pressures. Likewise, if the size of the two pistons is different and an equal amount of pressure is exerted on the pistons, the fluid will move. The pressure of the fluid while it is in motion is called **dynamic pressure**.

GASES

A gas is a fluid made up of independent particles—atoms or molecules—that are in constant, random motion. This means that a gas will fill any container into which it is placed. The random movement of gas particles also ensures that any two gases sharing the same container will totally mix. This is **diffusion**.

The kinetic energy of atoms and molecules increases as the temperature increases. Molecules in solids move slowly compared to those in liquids or gases. Gas molecules move quickly compared to liquid molecules. At higher temperatures, gas molecules spread out more, whereas at lower temperatures, gas molecules move closer together. The bombardment of particles against the sides of the container produces pressure.

Behavior of Gases

Three simple laws describe the predictable behavior of gases: Boyle's law, Charles' law, and the pressure (ideal gas) law. Each of these laws describes a relationship between the pressure, volume, and temperature of a gas.

Boyle's law states that the volume and pressure of a mass of gas at a fixed temperature are inversely proportional. If the pressure on a gas increases, its volume will decrease; likewise if the volume is increased, the pressure will decrease.

Charles' law states that the volume of a mass of gas depends on its temperature. Therefore, at a constant pressure, the volume of a gas will increase or decrease in relationship to its temperature increase or decrease. Increasing the temperature of the gas will increase its pressure. If the volume cannot change, the pressure of the gas will. Therefore, the pressure and temperature of a gas are also directly related. If you increase one, you also increase the other. This explains why cold air is denser than warm air.

In the event that all three variables—pressure, volume, and temperature—are changed, the ideal gas law allows for changes of two variables to utilize either Boyle's or Charles' law.

Air Pressure

Because air is gaseous matter with mass and weight, it exerts pressure on the earth's surface. A 1-square-inch column of air extending from the earth's surface to the outer edge of the atmosphere weighs 14.7 psi at sea level. Therefore, atmospheric pressure is 14.7 psi at sea level (**Figure 8-48**). **Atmospheric pressure** may be defined as the total weight of the earth's atmosphere. Pressure greater than atmospheric pressure may be measured in psi gauge (psig). Using

Figure 8-48 One square inch of air equals 14.7 pounds per square inch of pressure at sea level.

a standard pressure gauge, air pressure is compared to that of normal atmospheric pressure. When the actual pressure is 19.7 psi, the gauge will read 5 psi, showing the pressure differential (**Figure 8-49**). The actual pressure is referred to as psi absolute (psia).

When air becomes hotter, it expands, and this hotter air is lighter compared to an equal volume of cooler air. This hotter, lighter air exerts less pressure on the earth's surface compared to cooler air. This means the weight of the atmosphere changes with weather. This change is rather slight. As the weight changes, so does the atmospheric pressure. The

Figure 8-49 The relationship between psia and psig.

change in atmospheric pressure is measured with a barometer and is called **barometric pressure**. Barometric pressure at normal atmospheric pressure is 29.92 inches of mercury. The increments for measuring barometric pressure are based on the increments of a barometer. A barometer is a "J"-shaped tube with mercury in it. One end of the tube is exposed to normal atmospheric pressure and the other end to current atmospheric pressure. When the current atmospheric pressure equals normal atmospheric pressure, the level of the mercury will be 29.92 inches up the tall part of the "J." When the current atmospheric pressure is lower than normal, the normal atmospheric pressure pushes the mercury down. Likewise, when current atmospheric pressure is higher than normal, it will push the mercury up the tube. The amount of mercury movement reflects the difference in the two pressures. This corresponds with a universal law that states a high pressure always moves toward a lower pressure.

Although the pressure of the atmosphere only changes slightly, the impact of these changes can be critical to the overall operation of an engine. The combustion process depends on having the correct amount of air enter into the cylinders. If the calibrations for the air and the accompanying amount of fuel did not consider the changes in atmospheric pressure, the engine would most often not receive the correct mixture of air and fuel. Today's engines are equipped with a sensor to monitor barometric pressure.

To further consider the law that states a high pressure always moves to a lower pressure, look at what happens when a nail punctures an automotive tire. The high-pressure air in the tire leaks out until the pressure inside the tire is equal to the atmospheric pressure outside the tire. When the tire is repaired and inflated, air with a pressure higher than atmospheric is forced into the tire.

When you climb above sea level, atmospheric pressure decreases. The weight of a column of air is less at an elevation of 5,000 feet (1,524 meters) than it is at sea level. As altitude continues to increase, atmospheric pressure and weight continue to decrease. At an altitude of several hundred miles above sea level, the earth's atmosphere ends, and there is no pressure beyond that point (**Figure 8-50**).

Vacuum Scientifically, **vacuum** is defined as the absence of atmospheric pressure. However, it is commonly used to refer to any pressure less than atmospheric pressure. Vacuum may also be referred to as low or negative pressure simply because it is a pressure lower than atmospheric pressure.

Altitude in feet	Altitude in meters	Atmospheric pressure
Sea level	Sea level	14.7 psi
18,000	5,486.3	7.35 psi
52,926	16,131.9	1.47 psi
101,381	30,900.9	0.147 psi
159,013	48,467.2	0.0147 psi
227,889	69,463.6	0.00147 psi
283,076	96,281.6	0.000147 psi

Figure 8-50 The higher the altitude, the lower the pressure of the atmosphere.

Figure 8-51 A vacuum gauge measures pressures below atmospheric pressure in units of inches of mercury.

Vacuum could be measured in psig or psia, but inches of mercury (in. Hg) is most commonly used for this measurement (**Figure 8-51**). Let us assume that a plastic “U” tube is partially filled with mercury, and atmospheric pressure is allowed to enter one end of the tube. If vacuum is supplied to the other end of the “U” tube, the mercury is forced downward by the atmospheric pressure. When this movement occurs, the mercury also moves upward on the side where the vacuum is supplied. For example, if the mercury moves downward 10 inches, or 25.4 centimeters (cm) where the atmospheric pressure is supplied, and upward 10 in. (25.4 cm) where the vacuum is supplied, the mercury moved a total of 20 in. and the vacuum is rated as 20 in. Hg. The highest possible, or perfect, vacuum is approximately 29.9 in. Hg.

HEAT

Heat is a form of energy. The main sources of heat are the sun, the earth, chemical reactions, electricity, friction, and nuclear energy. Heat results from the kinetic energy that is present in all matter; therefore, everything has heat. Cold objects have low

From	To °F	To °C	To °K
°F	°F	$(°F - 32)/1.8$	$(°F - 32) \times 5/9 + 273.15$
°C	$(°C \times 1.8) + 32$	°C	°C + 273.15
°K	$(°K - 273.15) \times 9/5 + 32$	°K - 273.15	°K

Figure 8-52 Conversion guidelines for °F, °C, and °K.

kinetic energy because their atoms and molecules are moving very slowly, whereas hot objects have more kinetic energy because their atoms and molecules are moving fast.

Temperature is an indication of an object’s kinetic energy. Temperature is measured with a thermometer, which has a Fahrenheit (F), Celsius (Centigrade) (C), or Kelvin (K) scale (**Figure 8-52**). At absolute zero (-459.4°F , -273°C , or 0°Kelvin), particles of matter do not vibrate, but at all other temperatures, particles have motion. The temperature of an object is a statement of how cold or hot an object is. Heat and temperature are not the same thing: Heat is the movement of kinetic energy from one object to another, whereas temperature is an indication of the amount of kinetic energy something has. Energy from something hot will always move to an object that is colder until both are at the same temperature. The greater the difference in temperature between the two objects, the faster the heat will flow from one to the other.

Heat is measured in British thermal units (Btus) and calories. One Btu is the amount of heat required to heat 1 pound of water by 1 degree Fahrenheit. One calorie is equal to the amount of heat needed to raise the temperature of 1 gram of water 1 degree Celsius.

Heat Transfer

Heat transfers between two substances that have different temperatures through convection, conduction, or radiation. **Convection** is the transfer of heat by the movement of a heated object. Convection can be easily seen by watching a pot of water on a stove. The water on the bottom of the pot is the first to be heated by the stove. As the water at the bottom becomes hotter, it expands and becomes lighter than the water at the top of the pot. This causes the heavier water to sink toward the bottom and push the warmer water up. This continues until all of the water in the pot is at the same temperature.

Conduction is the movement of heat through a material. The immense heat that results from combustion is absorbed by the engine and is used to push the pistons down. The engine’s cooling system uses conduction to move the heat from the parts to help cool the engine. Because heat energy moves from

something hot toward something colder, the engine's heat moves to the engine's coolant circulating within the engine. Heat can be conducted to a liquid, gas, or solid.

Radiation does not rely on another material to transfer heat. The moving atoms and molecules within an object create waves of radiant energy. These waves are typically called infrared rays. Hot objects give off more infrared rays than colder objects. Therefore, a hot object will give off infrared rays to anything around it that is colder. No movement is necessary to transfer this heat. You can feel radiation in action by simply putting your hand near something that is hot. The hot object cools as it radiates its heat energy. In an engine's cooling system, the radiator uses radiation to transfer heat from the coolant to the surrounding air.

The Effects of Temperature Change

Anytime the temperature of an object changes, a transfer of heat has occurred. The change in temperature can also cause the object to change size or its state of matter. As heat moves in and out of a mass, the movement of atoms and molecules in that mass increases or slows down. With an increase in motion, the size of the mass tends to get bigger or expand. This is commonly called **thermal expansion**. **Thermal contraction** takes place when a mass has heat removed from it and the atoms and molecules slow down. All gases and most liquids and solids expand when heated, with gases expanding the most. Solids, because they are not fluid, expand and contract at a much lower rate. It is important to realize that all materials do not expand and contract at the same rate. For example, an aluminum component will

expand at a faster rate than the same component made of iron. This explains why aluminum cylinder heads have unique service requirements and procedures when compared to iron cylinder heads.

Thermal expansion takes place every time fuel and air are burned in an engine. The sudden temperature increase inside the cylinder causes a rapid expansion of the gases, which pushes the piston downward.

Typically when heat is added to a mass, the temperature of the mass increases. This does not always happen, however. In some cases, the additional heat causes no increase in temperature but causes the mass to change its state (solid to liquid or liquid to gas). For example, if we take an ice cube and heat it to 32°F (0°C), it will begin to melt (**Figure 8–53**). As heat is added to the ice cube, the temperature of the ice cube will not increase until it becomes a liquid. The heat added to the ice cube that did not raise its temperature but caused it to melt is called **latent heat** or the heat of fusion. Each gram of ice at 0°C requires 80 calories of heat to melt it to water at 0°C. As more heat is added to the 0°C water, the water's temperature will once again increase. This continues until the temperature of the water reaches 212°F (100°C). This is the boiling temperature of water. At this point, any additional heat applied to the water is latent heat, causing the water to change its state to that of a gas. This added heat is called the heat of evaporation.

To change the water gas back to liquid water, the same amount of heat required to change the liquid to a gas must be removed from the gas. At that point the gas condenses to a liquid. As additional heat is removed, the temperature will drop until enough

Figure 8-53 Water can exist in three different states of matter.

heat is removed to bring its temperature back down to freezing (melting in reverse) point. At that time latent heat must be removed from the liquid before the water turns to ice again.

Controlling Heat

There is a particular temperature range in which all parts of an automobile will operate best. Engineers strive to control those temperatures to ensure reliable and efficient operation. This is a major task because parts that do not perform well when hot are often mounted close to something that is very hot. High heat could transfer to the heat sensitive parts if insulation or passing outside air was not present. Although some parts tolerate extreme temperatures, they must still be protected from overheating. The combustion process can generate temperatures as great as 2,500°F (1,371°C). If that heat moved uncontrollably to other parts of the engine, those parts would expand to the point where they could no longer move or they may melt. This is why the engine's cooling system is so important. The cooling system is a controlled heat transfer system designed to protect the engine and allow it to run more efficiently.

CHEMICAL PROPERTIES

The properties of something describe or identify the characteristics of an object. Physical properties are characteristics that are readily observable, such as color, size, luster, and smell.

Chemical properties are only observable during a chemical reaction and describe how one type of matter reacts with another to form a new and different substance. Chemical properties are quite different from physical properties. A chemical property of some metals is the ability to combine with oxygen to form rust (iron and oxygen) or tarnish (silver and sulfur). Another example is hydrogen's ability to combine with oxygen to form water.

A solution is a mixture of two or more substances. Most solutions are liquids, but solutions of gases and solids are possible. An example of a gas solution is the air we breathe; it is composed of mostly oxygen and nitrogen. Brass is a good example of a solid solution because it is composed of copper and zinc. The liquid in a solution is called the **solvent**, and the substance added is the solute. If both are liquids, the one present in the smaller amount is usually considered the solute. Solutions can vary widely in terms of how much of the dissolved substance is actually present. A heavily diluted (much water) acid solution has very little acid and may not be noticeably acidic.

Specific Gravity

Specific gravity is the heaviness or relative **density** of a substance as compared to water. If something is 3.5 times as heavy as an equal volume of water, its specific gravity is 3.5. Its density is 3.5 grams per cubic centimeter, or 3.5 kilograms per liter. Specific gravity checks of a battery's electrolyte are an indication of the battery's state of charge (**Figure 8-54**).

Density is a statement of how much mass there is in a particular volume. Water is denser than air; therefore, there will be less air in a given container than water in that same container (**Figure 8-55**). The density of a material changes with temperature as well (**Figure 8-56**). This is the reason an engine runs more efficiently with cool intake air.

Chemical Reactions

Chemical changes, or chemical reactions, result in the production of another substance, such as wood turning to carbon after it has been completely burned. A chemical reaction is always accompanied by a change in energy. This means energy is given off or taken in during the reaction. Some reactions that release energy need some energy to get the reaction

Figure 8-54 Specific gravity checks of a battery's electrolyte are an indication of the battery's state of charge.

Substance	Density in g/cm ³
Air	0.0013
Ice	0.92
Water	1.00
Aluminum	2.70
Steel	7.80
Gold	19.30

Figure 8-55 A look at the density of different substances as compared to water.

started. A reaction takes place when two or more molecules interact and one of the following happens:

- A chemical change occurs.
- Single reactions occur as part of a large series of reactions.
- Ions, molecules, or pure atoms are formed.

Catalysts and Inhibitors

Reactions need a certain amount of energy to happen. A **catalyst** lowers the amount of energy needed to make a reaction happen. A catalyst is any substance that affects the speed of a chemical reaction without itself being consumed or changed. Catalysts tend to be highly specific, reacting with one substance or a small set of substances. In a car's catalytic converter, the platinum catalyst converts unburned hydrocarbons and nitrogen compounds into products that are harmless to the environment (**Figure 8-57**). Water, especially salt water, catalyzes oxidation and corrosion. An inhibitor is the opposite of a catalyst and stops or slows the rate of a reaction.

Acids/Bases

An ion is an atom or group of atoms with one or more positive or negative electric charges. Ions are formed when electrons are added to or removed from neutral

Figure 8-57 A basic catalytic converter that changes pollutants into chemicals that are good for the environment.

molecules or other ions. Ions are what make something an **acid** or a **base**.

Acids are compounds that break into hydrogen (H^+) ions and another compound when placed in an aqueous (water) solution. They have a sour taste, are corrosive, react with some metals to produce hydrogen, react with carbonates to produce carbon dioxide, change the color of litmus from blue to red, and become less acidic when combined with alkalis. Most acids are slow reacting, especially if they are weak acids. Acids also react with bases to form salts.

Alkalis (bases) are compounds that release hydroxide ions (OH^-) and react with H^+ ions to produce water, thus neutralizing each other. Most substances are neutral (not an acid or a base). Alkalis feel slippery, change the color of litmus from red to blue, and become less alkaline when they are combined with acids.

A hydroxide is any compound made up of one atom each of hydrogen and oxygen, bonded together and acting as the hydroxyl group or hydroxide anion (OH^-). An oxide is any chemical compound in which oxygen is combined with another element. Metal oxides typically react with water to form bases or with acids to form salts. Oxides of nonmetallic elements react with water to form acids or with bases to form salts.

A salt is a chemical compound formed when the hydrogen of an acid is replaced by a metal. Typically, an acid and a base react to form a salt and water.

pH The **pH scale** is used to measure how acidic or basic a solution is. Its name comes from the fact that pH is the absolute value of the power of the hydrogen ion concentration. The scale goes from 0 to 14. Distilled (pure) water is 7. Acids are found between 0 and 7 and bases are from 7 to 14. When the pH of a substance is low, the substance has many H^+ ions. When the pH is high, the substance has many OH^- ions. The pH value helps inform scientists, as well as technicians, of the nature, composition, or extent of reaction of substances.

The pH of something is typically checked with litmus paper. Litmus is a mixture of colored organic compounds obtained from several species of lichen. Lichen is a type of plant that is actually a combination of a fungus and algae. Litmus test strips can be used to check the condition of the engine's coolant (**Figure 8-58**).

Reduction and Oxidation

Oxidation is a chemical reaction in which a substance combines with oxygen. Rapid oxidation produces heat fast enough to cause a flame. When fuel burns, it

Figure 8-58 Litmus test strips can be used to check the condition of an engine's coolant.

combines with oxygen to form other compounds. This chemical reaction is combustion, which produces heat and fire.

The addition of hydrogen atoms or electrons is **reduction**. Oxidation and reduction always occur simultaneously: One substance is oxidized by the other, which is reduced. During oxidation, a molecule provides electrons. During reduction, a molecule accepts electrons. Oxidation and reduction reactions are usually called redox reactions. Redox is any chemical reaction in which electrons are transferred. Batteries, also known as voltaic cells, produce an electrical current at a constant voltage through redox reactions.

An oxidizing agent is something that accepts electrons and oxidizes something else while being reduced in the process. A reducing agent is something that provides electrons and reduces something else while being oxidized.

Every atom or ion has an oxidation number. This value compares the number of protons and electrons in that atom. In many cases, the oxidation number reflects the actual charge on the atom, but there are many cases in which it does not. The oxidation number is reduced during reduction by adding electrons. The oxidation number is increased during oxidation by removing electrons. All free, uncombined elements have an oxidation number of zero. Hydrogen,

in all its compounds except hydrides, has an oxidation number of +1. Oxygen, in all its compounds except peroxides, has an oxidation number of −2.

Metallurgy

Metallurgy is the art and science of extracting metals from their ores and modifying them for a particular use. This includes the chemical, physical, and atomic properties and structures of metals and the way metals are combined to form alloys. An **alloy** is a mixture of two or more metals. Steel is an alloy of iron plus carbon and other elements.

Metals have one or more of the following properties:

- Good heat and electric conduction
- Malleability—can be hammered, pounded, or pressed into a shape without breaking
- Ductility—can be stretched, drawn, or hammered without breaking
- High light reflectivity—can make light bounce off its surface
- The capacity to form positive ions in a solution and hydroxides rather than acids when their oxides meet water

About three-quarters of the elements are metals. The most abundant metals are aluminum, iron, calcium, sodium, potassium, and magnesium.

Rust and Corrosion The rusting of iron is an example of oxidation. Unlike fire, rusting occurs so slowly that little heat is produced. Iron combines with oxygen to form rust. The rate at which this occurs depends on several factors: temperature, surface area (more iron exposed for oxygen to reach), and catalysts (speed up a reaction but do not react and change themselves).

Corrosion is the wearing away of a substance due to chemical reactions. It occurs whenever a gas or liquid chemically attacks an exposed surface. This action is accelerated by heat, acids, and salts. Some materials naturally resist corrosion; others can be protected by painting, coatings, galvanizing, or anodizing.

Galvanizing involves the coating of zinc onto iron or steel to protect it against exposure to the atmosphere. If galvanizing is properly applied, it can protect the metals for 15 to 30 years or more.

Metals can be anodized for corrosion resistance, electrical insulation, thermal control, abrasion resistance, sealing, improving paint adhesion, and decorative finishing. Anodizing is a process that electrically deposits an oxide film from an aqueous solution onto the surface of a metal, often aluminum. During the

process, dyes can be added to the process to give the material a colored surface.

Hardness The hardness of something describes its resistance to scratching. **Hardening** is a process that increases the hardness of a metal, deliberately or accidentally, by hammering, rolling, carburizing, heat treating, tempering, or other processes. All of these deform the metal by compacting the atoms or molecules to make the material denser.

Carburizing hardens the surface of steel with heat. It increases the hardness of the outer surface while leaving the core relatively soft. The combination of a hard surface and soft interior withstands very high stress. It also has a low cost and offers flexibility for manufacturing. To carburize, the steel parts are placed in a carbonaceous environment (with charcoal, coke, and carbonates or carbon dioxide, carbon monoxide, methane, or propane) at a high temperature for several hours. The carbon diffuses into the surface of the steel, altering the crystal structure of the metal. Gears, ball and roller bearings, and piston pins are often carburized.

Heat treating changes the properties of a metal (including iron, steel, aluminum, copper, and titanium) by using heat. **Tempering** is the heat treating of metal alloys, particularly steel. For example, raising the temperature of hardened steel to 752°F (400°C) and holding it for a time before quenching it in oil decreases its hardness and brittleness and produces strong steel.

Solids under Tension

The atoms of a solid are closely packed, so solids have a greater density than most liquids and gases. The rigidity results from the strong attraction between its atoms. A force pulling on a solid moves these atoms farther apart, creating an opposing force called tension. If a force pushes on a solid, the atoms move closer together, creating compression. These are the principles of how springs function. Springs are used in many automotive systems, the most obvious of which are those used in suspension systems (**Figure 8-59**).

An elastic substance is a solid that gets larger under tension, gets smaller under compression, and returns to its original size when no force is acting on it. Most solids show some elastic behavior, but there is usually a limit to the force that the material can face. When excessive force is applied, the material will not return to its original size and it will be distorted or will break. The limit depends on the material's internal structure; for example, steel has a low elastic limit and can only be extended about 1% of its length, whereas

Figure 8-59 A coil spring for a suspension system.

rubber can be extended to about 1,000%. Another factor involved in elasticity is the cross-sectional area of the material.

Tensile strength is the ratio of the maximum load a material can support without breaking while being stretched. It is dependent on the cross-sectional area of the material. When stresses less than the tensile strength are removed, the material returns to its original size and shape. Greater stresses form a narrow, constricted area in the material, which is easily broken. Tensile strengths are measured in units of force per unit area.

Electrochemistry

Electrochemistry is concerned with the relationship between electricity and chemical change. Many spontaneous chemical reactions release electrical energy and some of these are used in batteries and fuel cells to produce electric power. The basis for electricity is the movement of electrons from one atom to another.

Electrolysis is an electrochemical process. During this process, electric current is passed through a substance, causing a chemical change. This change causes either a gain or loss of electrons. Electrolysis normally takes place in an electrolytic cell made of separated positive and negative electrodes immersed in an electrolyte.

An **electrolyte** is a substance that conducts current as a result of the breaking down of its molecules into positive and negative ions. The most familiar electrolytes are acids, bases, and salts that

ionize when dissolved in solvents such as water and alcohol. Ions drift to the electrode of the opposite charge and are the conductors of current in electrolytic cells.

ELECTRICITY AND ELECTROMAGNETISM

All electrical effects are caused by electric charges. There are two types of electric charges: positive and negative. These charges exert electrostatic forces on each other due to the strong attraction of electrons to protons. An electric field is the area on which these forces have an effect. Protons carry a positive charge, while electrons carry a negative charge. Atoms are normally neutral, having an equal number of protons and electrons, but an atom can gain or lose electrons. Electricity has many similarities with magnetism. For example, the lines of the electric fields between charges take the same form as the lines of magnetic force, so magnetic fields can be said to be an equivalent to electric fields. Charges of the same type repel, while charges of a different type attract (Figure 8–60).

Figure 8-60 (A) In a magnet, lines of force emerge from the north pole and travel to the south pole before passing through the magnet back to the north pole. (B) Unlike poles attract, while (C) similar poles repel each other.

Electricity

An electric circuit is simply the path in which an electric current flows. Electrons can be moved around a circuit by electrostatic forces. A circuit usually consists of a conductive material, such as a metal, where the electrons are held very loosely to their atoms, thus making electron movement possible. The strength of the electrostatic force is the voltage. The movement of the electric charge is called an electric current. The higher the voltage, the greater the current will be. But the current also depends on the thickness, length, temperature, and nature of the materials used as a conductor. Electrical resistance opposes the flow of electric current. Good conductors have low resistance, which means that a small amount of voltage will produce high current. In batteries, the dissolving of an electrode causes the freeing of electrons, resulting in their movement to another electrode and the formation of a current.

Magnets

Some materials are natural magnets; however, most magnets are produced. The materials used to make a permanent magnet are commonly called ferromagnetic materials. These are made of mostly heated iron compounds. The heat causes the atoms to shift direction, and once all of them point in the same direction, the metal becomes a magnet. This sets up two distinct poles called the north and south poles. The poles are at the ends of the magnet and there is an attraction between the two separate poles.

The lines of a magnetic field form closed lines of force from the north to the south. If another iron or steel object enters into the magnetic field, it is pulled into the magnet. If another magnet is introduced into the magnetic field, it will either move into the field or push away from it. This is the result of the natural attraction of a magnet from north to south. If the north pole of one magnet is introduced to the north pole of another, the two poles will oppose each other and will push away. If the south pole is introduced to the north pole of another, the two magnets will join together because the opposite poles are attracted to each other.

The strength of the magnetic force is uniform around the outside of the magnet. The force is strongest at the surface of the magnet and weakens with distance. If you double the distance from a magnet, the force is reduced by $\frac{1}{4}$.

The strength of a magnetic field is typically measured with a magnetometer and in units of Gauss (G).

Electromagnetism

Electrical current will produce magnetism that affects other objects in the same way as permanent magnets. The arrangement of force lines around a current-carrying conductor, its magnetic field, is circular. The magnetic effect of electrical current is increased by making the current-carrying wire into a coil (**Figure 8-61**).

When a coil of wire is wrapped around an iron bar, it is called an **electromagnet**. The magnetic field produced by the coil magnetizes the iron bar, strengthening the magnetic field. The strength of the magnetism produced depends on the number of windings in the coil and the amount of the current flowing in the coil.

Producing Electrical Energy

There are many ways to generate electricity. The most common is to use coils of wire and magnets in a generator. When a wire and magnet are moved relative to each other, a voltage is produced (**Figure 8-62**). In a generator, the wire is wound into a coil and the coil rotates within the field of the magnet. The more turns in the coil and the faster the coil moves, the greater

Figure 8-61 When current is passed through a conductor, such as a wire, magnetic lines of force are generated around the wire at right angles to the direction of the current flow.

CONDUCTOR MOVEMENT

Figure 8-62 Moving a conductor across magnetic lines of force induces a voltage in the conductor.

the voltage. The coils or magnets spin around at high speed, typically turned by steam pressure. The steam is usually generated by burning coal or oil, a process that releases unwanted pollutants. Renewable sources of electricity, such as hydroelectric power, wind power, solar energy, and geothermal power, produce only heat as an emission. Automotive generators are driven by the engine's crankshaft via a belt. In a generator, the kinetic energy of a spinning object is converted into electrical energy.

A solar cell converts the energy of light directly into electrical energy, using layers of semiconductors. Electricity is produced by causing electrons to leave the atoms in a semiconductor material. Each electron leaves behind a hole or gap. Other electrons move into the hole, leaving holes in their atoms. This process continues and forms a moving chain of electrons, which is electrical current.

Radio Waves

Electricity and magnetism are directly related. A changing electric field will produce a changing magnetic field, and vice versa. Whenever an electric charge accelerates, it gives out energy in the form of electromagnetic radiation. For example, electrons moving up and down a radio antenna produce a type of radiation known as radio waves. Electromagnetic radiation consists of oscillating electric and magnetic fields. There is a wide range of different types of electromagnetic radiation, called the electromagnetic spectrum, extending from low-energy radio waves to high-energy, short-wavelength gamma rays. This includes visible light and X-rays.

SUMMARY

- Matter is anything that occupies space, and it exists as a gas, liquid, or solid.
- All matter is made of many tiny particles called atoms and molecules.
- When a solid dissolves in a liquid, a solution is formed. Not all solids will dissolve; rather, the liquid is either absorbed or adsorbed.
- Materials that *absorb* fluids are permeable substances. Impermeable substances *adsorb* fluids.
- Energy is the ability to do work and all matter has energy.
- The total amount of energy never changes; it can only be transferred from one form to another, not created or destroyed.
- When energy is released to do work, it is called kinetic energy. Stored energy is called potential energy.
- Energy conversion occurs when one form of energy is changed to another form.
- Mass is the amount of matter in an object. Weight is a force and is measured in pounds or kilograms. Gravitational force gives the mass its weight.
- Volume is the amount of space occupied by an object.
- The volume of an engine's cylinders determines its size, expressed as displacement.
- The compression ratio of an engine is the ratio of the volume in the cylinder above the piston when the piston is at the bottom of its travel to the cylinder's volume above the piston when the piston is at its uppermost position.
- A force is a push or pull, which can be large or small, and can be applied to something by direct contact or from a distance.
- When an object moves in a circle, its direction is continuously changing and all changes in direction require a force. The forces required to maintain circular motion are called centripetal and centrifugal forces.
- Pressure is a force applied against an object and is measured in units of force per unit of surface area (pounds per square inch or kilograms per square centimeter).
- The greater the mass of an object, the greater the force needed to change its motion.
- When a force overcomes static inertia and moves an object, the object gains momentum. Momentum is the product of an object's weight times its speed.
- Speed is the distance an object travels in a set amount of time. Velocity is the speed of an object in a particular direction. Acceleration is the rate of speed increase. Deceleration is the reverse of acceleration, because it is the rate of the decrease in speed.
- Newton's laws of motion are: (1) an object at rest tends to remain at rest and an object in motion tends to remain in motion; (2) when a force acts on an object, the motion of the object will change; and (3) for every action there is an equal and opposite reaction.
- Friction is a force that slows or prevents motion of two moving objects that touch.
- Friction can be reduced in two main ways: by lubrication or by the use of rollers.
- Aerodynamics is the study of the effects of air on a moving object.
- When a force moves a certain mass a specific distance, work is done.
- A machine is any device used to transmit a force and, in doing so, changes the amount of force and/or its direction. Examples of simple machines are inclined planes, pulleys, levers, gears, and wheels and axles.

- Torque is a force that tends to rotate or turn things and is measured by the force applied and the distance traveled.
- Gear ratios express the mathematical relationship of one gear to another.
- Power is a measurement of the rate at which work is done and is measured in watts.
- Horsepower is the rate at which torque is produced.
- An oscillation is any single swing of an object back and forth between the extremes of its travel. When that motion travels through matter or space, it becomes a wave.
- How many times the vibration occurs in 1 second is called frequency and is commonly expressed in hertz (Hz), which is equal to one cycle per second. The amplitude of a vibration is its intensity or strength.
- Noise is any unwanted signal or sound and can be random or periodic.
- Light is a form of electromagnetic radiation. It travels in a straight line at 300 million meters per second.
- A gas will always fill a sealed container, whereas a liquid may not. A gas will also readily expand or compress according to the pressure exerted on it. Liquids are basically incompressible, which gives them the ability to transmit force.
- Hydraulics is the study of liquids in motion.
- Pascal constructed the first known hydraulic device and established what is known as Pascal's law of hydraulics.
- The pressure inside the hydraulic system is called static pressure because there is no fluid motion. The pressure of the fluid while it is in motion is called dynamic pressure.
- Boyle's law states that the volume and pressure of gas at a fixed temperature is inversely proportional.
- The pressure law states that the pressure exerted by a gas increases as the temperature of the gas is increased.
- Charles' law states that the volume of a mass of gas depends on its temperature.
- Atmospheric pressure is the total weight of the earth's atmosphere. Pressure greater than atmospheric pressure may be measured in psi gauge (psig); actual pressure is measured in psi absolute (psia).
- Scientifically, vacuum is defined as the absence of atmospheric pressure. However, it is commonly used to refer to any pressure less than atmospheric pressure.
- Heat is a form of energy caused by the movement of atoms and molecules and is measured in British thermal units (Btus) and calories.
- Temperature is an indication of an object's kinetic energy and is measured with a thermometer.
- Convection is the transfer of heat by the movement of a heated object.
- Conduction is the movement of heat through a material.
- Through radiation, heat is transferred by radiant energy.
- As heat moves in and out of a mass, the size of the mass tends to change.
- Sometimes additional heat causes no increase in temperature but causes the mass to change its state; this heat is called latent heat.
- The liquid in a solution is called the solvent, and the substance added is the solute.
- Specific gravity is the heaviness or density of a substance compared to that of water.
- A catalyst is a substance that affects a chemical reaction without being consumed or changed.
- An ion is an atom or group of atoms with one or more positive or negative electric charges. Ions are formed when electrons are added to or removed from neutral molecules or other ions. Ions are what make something an acid or a base.
- The pH scale is used to measure how acidic or basic a solution is.
- Oxidation is a chemical reaction in which a substance combines with oxygen. The addition of hydrogen atoms or electrons is called reduction.
- Hardening is a process that increases the hardness of a metal by hammering, rolling, carburizing, heat treating, tempering, or other processes.
- An elastic substance is a solid that gets larger under tension, smaller under compression, and returns to its original size when no force is acting on it.
- Tensile strength represents the maximum load a material can support without breaking when being stretched and is dependent on the cross-sectional area of the material.
- Electrolysis is an electrochemical process in which electric current is passed through a substance, causing a chemical change.
- An electrolyte is a substance or compound that conducts electric current as a result of the breaking

down of its molecules into positively and negatively charged ions.

- Any electrical current will produce magnetism. When a coil of wire is wrapped around an iron bar, it is called an electromagnet.
- The most common way to produce electricity is to use coils of wire and magnets in a generator.

REVIEW QUESTIONS

- Describe Newton's first law of motion and give an application of this law in automotive theory.
- In what four states does matter exist?
- Explain Newton's second law of motion and give an example of how this law is used in automotive theory.
- Describe six different forms of energy.
- Describe four different types of energy conversion.
- Explain why a rotating, tilted wheel moves in the direction of the tilt.
- Why are gases and liquids considered fluids?
- Describe the effects of static and dynamic balance.
- Describe the effect of temperature on the volume of a gas.
- The nucleus of an atom contains _____ and _____.
- Which of the following is the correct formula used to calculate engine displacement?
 - $\text{Displacement} = \pi \times R^2 \times L \times N$
 - $\text{Displacement} = \pi^2 \times R \times L \times N$
 - $\text{Displacement} = \pi \times D \times L \times N$
 - $\text{Displacement} = \pi \times D \times L^2 \times N$
- Work is calculated by multiplying _____ by _____.
- Energy may be defined as the ability to do _____.
- Name three types of simple machines.
- When one object is moved over another object, the resistance to motion is called _____.
- Weight is the measurement of the earth's _____ on an object.
- Torque is a force that does work with a _____ action.
- How are engines mounted in a vehicle and why?
- Vacuum is defined as the absence of _____.
- While discussing different types of energy: Technician A says that when energy is released to do work, it is called potential energy. Technician B says that stored energy is referred to as kinetic energy. Who is correct?
 - Technician A only
 - Technician B only
 - Both A and B
 - Neither A nor B
- While discussing friction in matter: Technician A says that friction creates heat. Technician B says that friction occurs in liquids, solids, and gases. Who is correct?
 - Technician A only
 - Technician B only
 - Both A and B
 - Neither A nor B
- While discussing mass and weight: Technician A says that mass is the measurement of an object's inertia. Technician B says that mass and weight may be measured in cubic inches. Who is correct?
 - Technician A only
 - Technician B only
 - Both A and B
 - Neither A nor B
- When applying the principles of work and force, _____.
 - work is accomplished when force is applied to an object that does not move
 - in the metric system the measurement for work is cubic centimeters
 - no work is accomplished when an object is stopped by mechanical force
 - if a 50-pound object is moved 10 feet, 500 ft.-lb of work are produced
- All these statements about energy and energy conversion are true, *except* _____.
 - thermal energy may be defined as light energy
 - chemical to thermal energy conversion occurs when gasoline burns
 - mechanical energy is defined as the ability to do work
 - mechanical to electrical energy conversion occurs when the engine drives the generator
- Which of the following is *not* a true statement about heat?
 - Whenever the temperature of something changes, a transfer of heat has occurred.
 - All matter expands when heated.
 - A change in temperature can cause the object to change size.
 - A change in temperature can cause the object to change its state of matter.

Section 2

ENGINES

CHAPTER

9

AUTOMOTIVE ENGINE DESIGNS AND DIAGNOSIS

OBJECTIVES

- Describe the various ways in which engines can be classified.
- Explain what takes place during each stroke of the four-stroke cycle.
- Outline the advantages and disadvantages of the inline and V-type engine designs.
- Define important engine measurements and performance characteristics, including bore and stroke, displacement, compression ratio, engine efficiency, torque, and horsepower.
- Outline the basics of diesel, stratified, and Miller-cycle engine operation.
- Explain how to evaluate the condition of an engine.
- List and describe nine abnormal engine noises.

INTRODUCTION TO ENGINES

The engine (**Figure 9-1**) provides the power to drive the vehicle's wheels. All automobile engines, both gasoline and diesel, are classified as internal-combustion engines because the combustion or burning that creates energy takes place inside the engine.

The biggest part of the engine is the cylinder block (**Figure 9-2**). The cylinder block is a large casting of metal that is drilled with holes to allow for the passage

of lubricants and coolant through the block and provide spaces for movement of mechanical parts. The block contains the cylinders, which are round passageways fitted with pistons. The block houses or holds the major mechanical parts of the engine.

The cylinder head fits on top of the cylinder block to close off and seal the top of the cylinder (**Figure 9-3**). The combustion chamber is an area into

Figure 9-1 Today's engines are complex, efficient machines.

Figure 9-2 A cylinder block for an eight-cylinder engine.

Figure 9-3 A cylinder head for a late-model inline four-cylinder engine. *Courtesy of Chrysler LLC*

which the air-fuel mixture is compressed and burned. The cylinder head contains all or most of the combustion chamber. The cylinder head also contains ports through which the air-fuel mixture enters and burned gases exit the cylinder and the bore for the spark plug.

The valve train is a series of parts used to open and close the intake and exhaust ports. A valve is a movable part that opens and closes the ports. A camshaft controls the movement of the valves. Springs are used to help close the valves.

The up-and-down motion of the pistons must be converted to rotary motion before it can drive the wheels of a vehicle. This conversion is achieved by linking the piston to a crankshaft with a connecting rod. The upper end of the connecting rod moves with the piston. The lower end of the connecting rod is attached to the crankshaft and moves in a circle. The end of the crankshaft is connected to the flywheel or flexplate.

Engine Construction

Modern engines are highly engineered power plants. These engines are designed to meet the performance and fuel efficiency demands of the public. Modern engines are made of lightweight engine castings and stampings; noniron materials (for example, aluminum, magnesium, fiber-reinforced plastics); and fewer and smaller fasteners to hold things together. These fasteners are made possible through computerized joint designs that optimize loading patterns. Each of these newer engine designs has its own distinct personality, based on construction materials, casting configurations, and design (**Figure 9-4**).

These modern engine-building techniques have changed how engine repair technicians make a living.

Figure 9-4 A typical late-model engine. *Courtesy of American Honda Motor Co., Inc.*

Before these changes can be explained, it is important to explain the “basics” of engine design and operation.

ENGINE CLASSIFICATIONS

Today’s automotive engines can be classified in several ways depending on the following design features:

- **Operational cycles.** Most technicians will generally come in contact with only four-stroke engines. However, a few older cars have used and some cars in the future will use a two-stroke engine.
- **Number of cylinders.** Current engine designs include 3-, 4-, 5-, 6-, 8-, 10-, and 12-cylinder engines.
- **Cylinder arrangement.** An engine can be flat (opposed), inline, or V-type. Other more complicated designs have also been used.
- **Valve train type.** Engine valve trains can be either the **overhead camshaft (OHC)** type or the camshaft in-block **overhead valve (OHV)** type. Some engines separate camshafts for the intake and exhaust valves. These are based on the OHC design and are called **double overhead camshaft (DOHC)** engines. V-type DOHC engines have four camshafts—two on each side.
- **Ignition type.** There are two types of ignition systems: spark and compression. Gasoline engines use a spark ignition system. In a spark ignition system, the air-fuel mixture is ignited by an electrical

spark. Diesel engines, or compression ignition engines, have no spark plugs. A diesel engine relies on the heat generated as air is compressed to ignite the air-fuel mixture for the power stroke.

- **Cooling systems.** There are both air-cooled and liquid-cooled engines in use. Nearly all of today's engines have liquid-cooling systems.
- **Fuel type.** Several types of fuel currently used in automobile engines include gasoline, natural gas, methanol, diesel, and propane. The most commonly used is gasoline although new fuels are being tested.

Four-Stroke Gasoline Engine

In a passenger car or truck, the engine provides the rotating power to drive the wheels through the transmission and driving axles. All automotive engines, both gasoline and diesel, are classified as internal combustion because the combustion or burning takes place inside the engine. These systems require an air-fuel mixture that arrives in the combustion chamber at the correct time and an engine constructed to withstand the temperatures and pressures created by the burning of thousands of fuel droplets.

The **combustion chamber** is the space between the top of the piston and the cylinder head. It is an enclosed area in which the fuel and air mixture is burned. The piston fits into a hollow metal tube, called a cylinder. The piston moves up and down in the cylinder.

This reciprocating motion must be converted to a rotary motion before it can drive the wheels of a vehicle. This change of motion is accomplished by connecting the piston to a crankshaft with a connecting rod (**Figure 9-5**). The upper end of the connecting rod moves with the piston as it moves up and down in

the cylinder. The lower end of the connecting rod is attached to the crankshaft and moves in a circle. The end of the crankshaft is connected to the flywheel, which transfers the engine's power through the drive-train to the wheels.

In order to have complete combustion in an engine, the right amount of fuel must be mixed with the right amount of air. This mixture must be compressed in a sealed container, then shocked by the right amount of heat (spark) at the right time. When these conditions exist, all the fuel that enters a cylinder is burned and converted to power, which is used to move the vehicle. Automotive engines have more than one cylinder. Each cylinder should receive the same amount of air, fuel, and heat, if the engine is to run efficiently.

Although the combustion must occur in a sealed cylinder, the cylinder must also have some means of allowing heat, fuel, and air into it. There must also be a means to allow the burnt air-fuel mixture out so a fresh mixture can enter and the engine can continue to run. To accommodate these requirements, engines are fitted with valves.

There are at least two valves at the top of each cylinder. The air-fuel mixture enters the combustion chamber through an intake valve and leaves (after having been burned) through an exhaust valve (**Figure 9-6**). The valves are accurately machined plugs that fit into machined openings. A valve is said to be seated or closed when it rests in its opening. When the valve is pushed off its seat, it opens.

A rotating camshaft, driven and timed to the crankshaft, opens and closes the intake and exhaust valves. **Cams** are raised sections of a shaft that have high spots called **lobes**. Cam lobes are oval shaped. The placement of the lobe on the shaft determines when the valve will open. The height and shape of the lobe determines how far the valve will open and how

Figure 9-5 The linear (reciprocating) motion of the pistons is converted to rotary motion by the crankshaft.

Figure 9-6 A cutaway of an engine showing the intake passages (blue) and valve and exhaust passage (red) and valve.

Figure 9-7 The height and width of a cam lobe determine when and for how long a valve will be open.

long it will remain open in relation to piston movement (**Figure 9-7**).

As the camshaft rotates, the lobes rotate and push the valve open by pushing it away from its seat. Once the cam lobe rotates out of the way, the valve, forced by a spring, closes. The camshaft can be located either in the cylinder block or in the cylinder head.

When the action of the valves and the spark plug is properly timed to the movement of the piston, the combustion cycle takes place in four strokes of the piston: the intake stroke, the compression stroke, the power stroke, and the exhaust stroke. The camshaft is driven by the crankshaft through gears, or sprockets, and a cogged belt, or timing chain. The camshaft turns at half the crankshaft speed and rotates one complete turn during each complete four-stroke cycle.

Four-Stroke Cycle A **stroke** is the full travel of the piston either up or down in a cylinder's bore. The reciprocal movement of the piston during the four strokes is converted to a rotary motion by the

crankshaft. It takes two full revolutions of the crankshaft to complete the four-stroke cycle. One full revolution of the crankshaft is equal to 360 degrees of rotation; therefore, it takes 720 degrees to complete the four-stroke cycle. During one piston stroke, the crankshaft rotates 180 degrees.

Flywheel The piston moves by the pressure produced during combustion, but this moves the piston only about half a stroke or one-quarter of a revolution of the crankshaft. This explains why a flywheel is needed. The flywheel stores some of the power produced by the engine. This power is used to keep the pistons in motion during the rest of the four-stroke cycle. A heavy flywheel is only found on engines equipped with a manual transmission. Engines with automatic transmissions have a flexplate and a torque converter. The weight and motion of the fluid inside the torque converter serve as a flywheel.

Intake Stroke The first stroke of the cycle is the intake stroke. As the piston moves away from **top dead center (TDC)**, the intake valve opens (**Figure 9-8A**). The downward movement of the piston increases the volume of the cylinder above it, reducing the pressure in the cylinder. This reduced pressure, commonly referred to as engine vacuum, causes the atmospheric pressure to push a mixture of air and fuel through the open intake valve. (Some engines are equipped with a super- or turbocharger that pushes more air past the valve.) As the piston reaches the bottom of its stroke, the reduction in pressure stops, causing the intake of air-fuel mixture to slow down. It does not stop because of the weight and movement of the air-fuel mixture. It continues to enter the cylinder until the intake valve closes. The intake valve closes after the piston has reached **bottom dead center (BDC)**. This delayed closing of the valve increases the volumetric efficiency of the cylinder by packing as much air and fuel into it as possible.

Compression Stroke The compression stroke begins as the piston starts to move from BDC. The intake valve closes, trapping the air-fuel mixture in the cylinder (**Figure 9-8B**). The upward movement of the piston compresses the air-fuel mixture, thus heating it up. At TDC, the piston and cylinder walls form a combustion chamber in which the fuel will be burned. The volume of the cylinder with the piston at BDC compared to the volume of the cylinder with the piston at TDC determines the compression ratio of the engine.

Power Stroke The power stroke begins as the compressed fuel mixture is ignited (**Figure 9-8C**). With

Figure 9-8 (A) Intake stroke, (B) compression stroke, (C) power stroke, and (D) exhaust stroke.

the valves still closed, an electrical spark across the electrodes of a spark plug ignites the air-fuel mixture. The burning fuel rapidly expands, creating a very high pressure against the top of the piston. This drives the piston down toward BDC. The downward movement of the piston is transmitted through the connecting rod to the crankshaft.

Exhaust Stroke The exhaust valve opens just before the piston reaches BDC on the power stroke

(Figure 9-8D). Pressure within the cylinder causes the exhaust gas to rush past the open valve and into the exhaust system. Movement of the piston from BDC pushes most of the remaining exhaust gas from the cylinder. As the piston nears TDC, the exhaust valve begins to close as the intake valve starts to open. The exhaust stroke completes the four-stroke cycle. The opening of the intake valve begins the cycle again. This cycle occurs in each cylinder and is repeated over and over, as long as the engine is running.

Firing Order

An engine's **firing order** states the sequence in which an engine's pistons are on their power stroke and therefore the order in which the cylinders' spark plugs fire. The firing order also indicates the position of all of the pistons in an engine when a cylinder is firing. For example, consider a four-cylinder engine with a firing order of 1-3-4-2. The sequence begins with piston #1 on the compression stroke. During that time, piston #3 is moving down on its intake stroke, #4 is moving up on its exhaust stroke, and #2 is moving down on its power stroke. These events are identified by what needs to happen in order for #3 to be ready to fire next, and so on.

The firing order of an engine is determined by its design and manufacturer's preference. An engine's firing order can be found on the engine or on the engine's emissions label and in service manuals. **Figure 9-9** shows some of the common cylinder arrangements and their associated firing orders.

COMMON CYLINDER NUMBERING AND FIRING ORDER			
IN-LINE			
4-Cylinder		6-Cylinder	
① ② ③ ④		① ② ③ ④ ⑤ ⑥	
Firing Order	1-3-4-2	Firing Order	1-5-3-6-2-4

Figure 9-9 Examples of cylinder numbering and firing orders.

Figure 9-10 A two-stroke cycle.

Two-Stroke Gasoline Engine

In the past, several imported vehicles have used two-stroke engines. As the name implies, this engine requires only two strokes of the piston to complete all four operations: intake, compression, power, and exhaust (**Figure 9-10**). This is accomplished as follows:

1. Movement of the piston from BDC to TDC completes both intake and compression.
2. When the piston nears TDC, the compressed air-fuel mixture is ignited, causing an expansion of the gases. During this time, the intake and exhaust ports are closed.
3. Expanding gases in the cylinder force the piston down, rotating the crankshaft.
4. With the piston at BDC, the intake and exhaust ports are both open, allowing exhaust gases to leave the cylinder and air-fuel mixture to enter.

Although the two-stroke-cycle engine is simple in design and lightweight because it lacks a valve train, it has not been widely used in automobiles. It tends to be less fuel efficient and releases more pollutants into the atmosphere than four-stroke engines. Oil is often in the exhaust stream because these engines require constant oil delivery to the cylinders to keep the piston lubricated. Some of these engines require a certain amount of oil to be mixed with the fuel.

Engine Rotation To meet the standards set by the SAE, nearly all engines rotate in a counterclockwise direction. This can be confusing because its apparent direction changes with what end of the engine you look at. If one looks at the front of the engine, it rotates in a clockwise direction. The standards are based on the rotation of the flywheel, which is at the rear of

Figure 9-11 Normal combustion. Courtesy of Federal-Mogul Corporation

the engine, and there the engine rotates counter-clockwise.

Combustion

Although many different things and events can affect combustion in the engine's cylinders, the ignition system has the responsibility for beginning and maintaining the combustion process. Obviously when combustion does not occur in all of the cylinders, the engine will not run. If combustion occurs in all but one or two cylinders, the engine may start and run but will run poorly. The lack of combustion is not always caused by the ignition system. Poor combustion can also be caused by problems in the engine, air-fuel system, or the exhaust system.

When normal combustion occurs, the burning process moves from the gap of the spark plug across the compressed air-fuel mixture. The movement of this flame front should be rapid and steady and should end when all of the air-fuel mixture has been burned (**Figure 9-11**). During normal combustion, the rapidly expanding gases push down on the piston with a powerful but constant force.

When all of the air and fuel in the cylinder are involved in the combustion process, complete combustion has occurred. When something prevents this, the engine will misfire or experience incomplete combustion. Misfires cause a variety of driveability problems, such as a lack of power, poor gas mileage, excessive exhaust emissions, and a rough running engine.

Engine Configurations

Depending on the vehicle, either an inline, V-type, slant, or opposed cylinder design can be used. The most popular designs are inline and V-type engines.

Inline Engine In the inline engine design (**Figure 9-12**), the cylinders are all placed in a single row. There is one crankshaft and one cylinder head for all of the cylinders. The block is cast so that all cylinders are located in an upright position.

Figure 9-12 The cylinder block for an inline engine. Courtesy of Chrysler LLC

Inline engine designs have certain advantages and disadvantages. They are easy to manufacture and service. However, because the cylinders are positioned vertically, the front of the vehicle must be higher. This affects the aerodynamic design of the car. Aerodynamic design refers to the ease with which the car can move through the air. When equipped with an inline engine, the front of a vehicle cannot be made as low as it can with other engine designs.

V-Type Engine The V-type engine design has two rows of cylinders (**Figure 9-13**) located 60 to 90 degrees away from each other. A V-type engine uses one crankshaft, which is connected to the pistons on both sides of the V. This type of engine has two cylinder heads, one over each row of cylinders.

One advantage of using a V-configuration is that the engine is not as high or long as one with an inline

Figure 9-13 A V-type engine. *Courtesy of Chrysler LLC*

configuration. The front of a vehicle can now be made lower. This design improves the outside aerodynamics of the vehicle. If eight cylinders are needed for power, a V-configuration makes the engine much shorter, lighter, and more compact. Many years ago, some vehicles had an inline eight-cylinder engine. The engine was very long and its long crankshaft also caused increased torsional vibrations in the engine.

A variation of the V-type engine is the W-type engine. These engines are basically two V-type engines joined together at the crankshaft. This design makes the engine more compact. They are commonly found in late-model Volkswagens.

Slant Cylinder Engine Another way of arranging the cylinders is in a slant configuration. This arrangement is much like an inline engine, except the entire block has been placed at a slant. The slant engine was designed to reduce the distance from the top to the bottom of the engine. Vehicles using the slant engine can be designed more aerodynamically.

Opposed Cylinder Engine In this design, two rows of cylinders are located opposite the crankshaft (**Figure 9-14**). These engines have a common crankshaft and a cylinder head on each bank of cylinders. Porsches and Subarus use this style of engine, commonly called a boxer engine. Boxer engines have a low center of gravity and tend to run smoothly during all operating conditions.

Camshaft and Valve Location

The valves in all modern engines are placed in the cylinder head above the top of the piston. The valves in many older engine designs were placed to the side of the piston. Camshafts are located inside the engine

Figure 9-14 A horizontally opposed cylinder engine, commonly called a boxer engine.

Figure 9-15 The basic valve train for an overhead valve engine.

block or above the cylinder head. The placement of the camshaft further describes an engine.

Overhead Valve (OHV) As the name implies, the intake and exhaust valves in an OHV engine are mounted in the cylinder head and are operated by a camshaft located in the cylinder block. This arrangement requires the use of valve lifters, pushrods, and rocker arms to transfer camshaft rotation to valve movement (**Figure 9-15**).

Overhead Cam (OHC) An OHC engine also has the intake and exhaust valves located in the cylinder head. But as the name implies, the cam is located in the cylinder head. In an OHC engine, the valves are operated directly by the camshaft or through cam followers or tappets (**Figure 9-16**). Engines with one camshaft above a cylinder are often referred to as single overhead camshaft (SOHC) engines.

Figure 9-16 Basic valve and camshaft placement in an overhead camshaft engine. Courtesy of Hyundai Motor America

Engine Location

The engine is usually placed in one of three locations. In most vehicles, it is located at the front of the vehicle, in front of the passenger compartment. Front-mounted engines can be positioned either longitudinally or transversely with respect to the vehicle.

The second engine location is a mid-mount position between the passenger compartment and rear suspension. Mid-mount engines are normally transversely mounted. The third, and least common, engine location is the rear of the vehicle. The engines are typically opposed-type engines.

Each of these engine locations offers advantages and disadvantages.

Front Engine Longitudinal In this type of vehicle, the engine, transmission, front suspension, and steering equipment are installed in the front of the body, and the differential and rear suspension are installed in the rear of the body. Most front engine longitudinal vehicles are rear-wheel drive. Some front-wheel-drive cars with a transaxle have this configuration, and most four-wheel-drive vehicles are equipped with a transfer case and have the engine mounted longitudinally in the front of the vehicle.

Total vehicle weight can be evenly distributed between the front and rear wheels with this configuration. This lightens the steering force and equalizes the braking load. With this design, it is possible to independently remove and install the engine,

propeller shaft, differential, and suspension. Longitudinally mounted engines require large engine compartments. The need for a rear-drive propeller shaft and differential also cuts down on passenger compartment space.

Front Engine Transverse Front engines that are mounted transversely sit sideways in the engine compartment. They are used with transaxes that combine transmission and differential gearing into a single compact housing, fastened directly to the engine. Transversely mounted engines reduce the size of the engine compartment and overall vehicle weight.

Transversely mounted front engines allow for down-sized, lighter vehicles with increased interior space. However, most of the vehicle weight is toward the front of the vehicle. This provides for increased traction by the drive wheels. The weight also places a greater load on the front suspension and brakes.

Mid-Engine Transverse In this design, the engine and drivetrain are positioned between the passenger compartment and rear axle. Mid-engine location is used in smaller, rear-wheel-drive, high-performance sports cars for several reasons. The central location of heavy components results in a center of gravity very near the center of the vehicle, which vastly improves steering and handling. Since the engine is not under the hood, the hood can be sloped downward, improving aerodynamics and increasing the driver's field of vision. However, engine access and cooling efficiency are reduced. A barrier is also needed to reduce the transfer of noise, heat, and vibration to the passenger compartment.

ENGINE MEASUREMENT AND PERFORMANCE

Many of the engine measurements and performance characteristics a technician should be familiar with were discussed in Chapter 8. What follows are some of the important facts of each.

Bore and Stroke

The **bore** of a cylinder is simply its diameter measured in inches (in.) or millimeters (mm). The stroke is the length of the piston travel between TDC and BDC. Between them, bore and stroke determine the displacement of the cylinders. When the bore and stroke are of equal size, the engine is called a *square engine*. Engines that have a larger bore than stroke are called oversquare and engines with a larger stroke than bore are referred to as being undersquare. **Oversquare** engines offer the opportunity to fit larger valves in the

Figure 9-17 The stroke of an engine is equal to twice the crank throw.

combustion chamber and use longer connecting rods, which means oversquare engines are capable of running at higher engine speeds. But because of the size of the bore, the engines tend to be physically larger than undersquare engines. **Undersquare** engines have short connecting rods that aid in the production of more power at lower engine speeds. A square engine is a compromise between the two designs.

The **crank throw** is the distance from the crankshaft's main bearing centerline to the connecting rod journal centerline. The stroke of any engine is twice the crank throw (**Figure 9-17**).

Displacement

A cylinder's displacement is the volume of the cylinder when the piston is at BDC. An engine's displacement is the sum of the displacements of each of the engine's cylinders (**Figure 9-18**). Typically, an engine with a larger displacement produces more torque than a smaller displacement engine; however, many other factors influence an engine's power output. Engine displacement can be changed by changing the size of the bore and/or stroke of an engine.

Calculation of an engine's displacement is given in Chapter 8.

The throw of a crankshaft determines the stroke. The length of the connecting rod only determines where the piston will be as it travels through the stroke. Therefore, it is possible that the piston may reach out above its bore if a crankshaft with a longer stroke is installed with standard connecting rods. The correct combination of pistons with a higher piston pin hole must be used to prevent damage to the engine.

Figure 9-18 Displacement is the volume the cylinder holds between TDC and BDC.

Compression Ratio

An engine's stated compression ratio is a comparison of a cylinder's volume when the piston is at BDC to the cylinder's volume when the piston is at TDC. The compression ratio is a statement of how the air-fuel mixture is compressed during the compression stroke. It is important to keep in mind that this ratio can change through wear and carbon and dirt buildup in the cylinders. For example, if a great amount of carbon collects on the top of the piston and around the combustion chamber, the volume of the cylinder changes. This buildup of carbon will cause the compression ratio to increase because the volume at TDC will be smaller.

The higher the compression ratio, the more power an engine theoretically can produce. Also, as the compression ratio increases, the heat produced by the compression stroke also increases. Gasoline with a low-octane rating burns fast and may explode rather than burn when introduced to a high-compression ratio, which can cause preignition. The higher a gasoline's octane rating, the less likely it is to explode.

As the compression ratio increases, the octane rating of the gasoline should also be increased to prevent abnormal combustion.

Performance TIP

Often the bore of an engine is cut larger to incorporate larger pistons and to increase the engine's displacement. Doing this increases the power output of the engine. However, this will also increase the engine's compression ratio. The compression ratio may also be increased by removing metal from the mating surface of the cylinder head and/or the engine block or by installing a thinner head gasket. Care must be taken not to raise the compression too high. High-compression ratios require high-octane fuels and if the required fuel is not available, any performance gains can be lost. Use this formula to determine the exact compression ratio of an engine after modifications have been made:

$$CR = \frac{\text{total cylinder volume with the piston at BDC}}{\text{the total cylinder volume with the piston at TDC}}$$

The volume at BDC is equal to the cylinder's volume when the piston is at BDC plus the volume of the combustion chamber plus the volume of the head gasket. The volume of the head gasket is calculated by multiplying its thickness by the square of the bore and 0.7854.

The volume at TDC is equal to the volume in the cylinder when the piston is at TDC plus the volume of the combustion chamber plus the volume of the head gasket.

Engine Efficiency

One of the dominating trends in automotive design is increasing an engine's efficiency. **Efficiency** is simply a measure of the relationship between the amount of energy put into an engine and the amount of energy available from the engine. Other factors, or efficiencies, affect the overall efficiency of an engine.

Volumetric Efficiency Volumetric efficiency describes the engine's ability to have its cylinders filled with air-fuel mixture. If the engine's cylinders are able to be filled with air-fuel mixture during its intake stroke, the engine has a volumetric efficiency of 100%. Typically, engines have a volumetric efficiency of 80% to 100% if they are not equipped with a turbo- or supercharger. Basically, an engine becomes more efficient as its volumetric efficiency is increased.

Thermal Efficiency Thermal efficiency is a measure of how much of the heat formed during the combustion process is available as power from the

Figure 9-19 A gasoline engine is only about 25% thermal efficient.

engine. Typically only one-fourth of the heat is used to power the vehicle. The rest is lost to the surrounding air and engine parts and to the engine's coolant (**Figure 9-19**). Obviously, when less combustion heat is lost, the engine is more efficient.

Mechanical Efficiency Mechanical efficiency is a measure of how much power is available once it leaves the engine compared to the amount of power that was exerted on the pistons during the power stroke. Power losses occur because of the friction generated by the moving parts. Minimizing friction increases mechanical efficiency.

Torque versus Horsepower

Torque is a twisting or turning force. Horsepower is the rate at which torque is produced. An engine produces different amounts of torque based on the rotational speed of the crankshaft and other factors. A mathematical representation, or graph, of the relationship between the horsepower and torque of an engine is shown in **Figure 9-20**.

This graph shows that torque begins to decrease when the engine's speed reaches about 1,700 rpm. Brake horsepower increases steadily until about 3,500 rpm. Then it drops. The third line on the graph indicates the horsepower needed to overcome the friction or resistance created by the internal parts of the engine rubbing against each other.

Brake horsepower is a term used to express the amount of horsepower measured on a dynamometer. This measurement represents the amount of horsepower an engine provides when it is held at a specific speed at full throttle. Horsepower is also

Figure 9-20 The relationship between horsepower and torque.

expressed as SAE gross horsepower, which is the maximum amount of power an engine produces at a specified speed with some of its accessories disconnected or removed. SAE net horsepower represents the power produced by an engine at a specified speed when all of its accessories are operating.

Atkinson Cycle Engines

An **Atkinson cycle** engine is a four-stroke cycle engine in which the intake valve is held open longer than normal during the compression stroke (**Figure 9-21**). As the piston is moving up, the mixture is being compressed and some of it pushed back into the intake manifold. As a result, the amount of mixture in the cylinder and the engine's

effective displacement and compression ratio are reduced. Typically there is a "surge tank" in the intake manifold to hold the mixture that is pushed out of the cylinder during the Atkinson compression stroke. Often the Atkinson cycle is referred to as a five-stroke cycle because there are two distinct cycles during the compression stroke. The first is while the intake valve is open and the second is when the intake valve is closed. This two-stage compression stroke creates the "fifth" cycle.

In a conventional engine, much engine power is lost due to the energy required to compress the mixture during the compression stroke. The Atkinson cycle reduces this power loss and this leads to greater engine efficiency. The Atkinson cycle also effectively changes the length of time the mixture is being compressed. Most Atkinson cycle engines have a long piston stroke. Keeping the intake valve open during compression effectively shortens the stroke. However, because the valves are closed during the power stroke, that stroke is long. The longer power stroke allows the combustion gases to expand more and reduces the amount of heat that is lost during the exhaust stroke. As a result, the engine runs more efficiently than a conventional engine.

Although these engines provide improved fuel economy and lower emissions, they also produce less power. The lower power results from the lower operating displacement and compression ratio. Power also is lower because these engines take in less air than a conventional engine.

Hybrid Engines Many hybrid vehicles have Atkinson cycle engines. The low-power output from the engine is supplemented with the power from the electric motors. This combination offers good fuel economy, low emissions, and normal acceleration.

Some Toyota Atkinson cycle engines use variable valve timing to allow the engine to run with low displacement (Atkinson cycle) or normal displacement. The opening and closing of the intake valves is controlled by the engine control system (**Figure 9-22**). While the valve is open during the compression stroke, the effective displacement of the engine is reduced. When the displacement is low, fuel consumption is minimized, as are exhaust emissions. The engine runs with normal displacement when the intake valves close earlier. This action provides for more power output. The control unit adjusts valve timing according to engine speed, intake air volume, throttle position, and water temperature. Because this system responds to operating conditions, the displacement of the engine changes accordingly.

Figure 9-21 (A) Typical valve timing for an Atkinson cycle engine. (B) Typical valve timing for a conventional four-stroke cycle engine. Notice that the intake valve in the Atkinson cycle engine opens and closes later.

Figure 9-22 Toyota's VVT-i (variable valve timing with intelligence) changes the engine from a conventional four-stroke cycle to an Atkinson cycle according to the vehicle's operating conditions.

In response to these inputs, the control unit sends commands to the camshaft timing oil control valve. A controller at the end of the camshaft is driven by the crankshaft. The control unit regulates the oil pressure sent to the controller. A change in oil pressure changes the position of the camshaft and the timing of the valves. The camshaft timing oil control valve is duty cycled by the control unit to advance or retard intake valve timing. The controller rotates the intake camshaft in response to the oil pressure. An advance in timing results when oil pressure is applied to the timing advance chamber. When the oil control valve is moved and the oil pressure is applied to the timing retard side vane chamber (**Figure 9-23**), the timing is retarded.

Miller Cycle Engines An Atkinson cycle engine with forced induction (supercharging) is called a Miller cycle engine. The decrease of intake air and resulting low power is compensated by the supercharger. The supercharger forces air into the cylinder during the compression stroke. Keep in mind that the actual compression stroke in an Atkinson cycle engine does not begin until the intake valve closes. The supercharger in a Miller cycle engine forces more air past the valve and, therefore, there is more air in the cylinder when the intake closes.

The Miller cycle is efficient only if the supercharger uses less energy to compress the mixture than the piston would normally need to compress it during a normal compression stroke. This is an obstacle for engineers because to drive a supercharger requires approximately 10% to 20% of the engine's output. The latest Miller cycle engines control the action of the supercharger so that it is only used when it is better for compression and is shut down when piston compression is best.

DIESEL ENGINES

Diesel engines represent tested, proven technology with a long history of success. Invented by Dr. Rudolph Diesel, a German engineer, and first marketed in 1897, the diesel engine is now the dominant power plant in heavy-duty trucks, construction equipment, farm equipment, buses, and marine applications. Diesel engines in cars and light trucks will become more common soon. There are many reasons for this, one of which is that low-sulfur diesel fuel will be available in the United States. Diesel vehicles are very common in Europe and other places where cleaner fuels are available (**Figure 9-24**).

The operation of a **diesel engine** is comparable to a gasoline engine. They also have a number of

Figure 9-23 Oil flow for the VVT-i as it advances and retards the valve timing.

Figure 9-24 A European four-cylinder passenger car diesel engine.

components in common, such as the crankshaft, pistons, valves, camshaft, and water and oil pumps. They both are available as two- or four-stroke combustion cycle engines. However, diesel engines have compression ignition systems (**Figure 9-25**). Rather than relying on a spark for ignition, a diesel engine uses the heat produced by compressing air in the combustion chamber to ignite the fuel. The compression ratio of diesel engines is typically three times (as high as 25:1) that of a gasoline engine. As intake air is compressed, its temperature rises to 1,300°F to 1,650°F (700°C to 900°C). Just before the air is fully compressed, a fuel injector sprays a small amount of diesel fuel into the cylinder. The high temperature of the compressed air instantly ignites the fuel. The combustion causes increased heat in

Figure 9-25 A four-stroke diesel engine cycle.

the cylinder and the resulting high pressure moves the piston down on its power stroke.

Construction

Diesel engines are heavier than gasoline engines of the same power. A diesel engine must be made stronger to contain the extremely high compression and combustion pressures. A diesel engine also produces less horsepower than a same-sized gasoline engine. Therefore, to provide the required power, the displacement of the engine is increased. This results in a physically larger engine. Diesels have high torque outputs at very low engine speeds but do not run well at high engine speeds. On many diesel engines, turbochargers and inter-coolers are used to increase their power output (**Figure 9-26**).

Diesel combustion chambers are different from gasoline combustion chambers because diesel fuel burns differently. Three types of combustion chambers are used in diesel engines: open combustion chamber, precombustion chamber, and turbulence combustion chamber. The open combustion chamber is located directly inside the piston. Diesel fuel is injected directly into the center of the chamber. The shape of the chamber and the quench area produce turbulence. The precombustion chamber is a smaller, second chamber connection to the main combustion chamber. On the power stroke, fuel is injected into the small chamber. Combustion is started there and then spreads to the main chamber. This design allows for lower fuel injection pressures and simpler injection systems. The turbulence combustion chamber creates an increase in air velocity or turbulence in the combustion chamber. The fuel is injected into the turbulent air and burns more completely.

Fuel injection is used on all diesel engines. Older diesel engines had a distributor-type injection

Figure 9-26 The high-output Cummins turbo diesel I-6 engine used in Dodge Ram heavy-duty trucks. *Courtesy of Chrysler LLC*

pump driven and regulated by the engine. The pump supplied fuel to injectors that sprayed the fuel into the engine's combustion chamber. Newer diesel engines are equipped with common rail systems (**Figure 9-27**). Common rail systems are **direct injection (DI)** systems. The injectors' nozzles are placed inside the combustion chamber. The piston top has a depression where initial combustion takes place. The injector must be able to withstand the temperature and pressure inside the cylinder and must be able to deliver a fine spray of fuel into those conditions. These systems have a high-pressure (14,500+ psi or 1,000+ bar) fuel rail connected to individual solenoid-type injectors.

Figure 9-27 A common rail fuel injection system.

The injectors are controlled by a computer that attempts to match injector operation to the operating conditions of the engine. Newer diesel fuel injectors rely on stacked piezoelectric crystals rather than solenoids. Piezo crystals quickly expand when electrical current is applied to them. The crystals allow the injectors to respond very quickly to the needs of the engine. With this new-style injector, diesel engines are quieter, more fuel efficient, cleaner, and have more power.

Diesel engines are also available in two-stroke cycle models. Most diesels generally use the four-stroke cycle, while some larger diesels operate with the two-stroke cycle. Two-stroke diesels must use forced induction from either a turbocharger or a supercharger. These engines are ideal for some applications because they provide high torque for their displacement.

Advantages

When compared to gasoline engines, diesel engines offer many advantages. They are more efficient and use less fuel than a gasoline engine of the same size. Diesel engines are very durable. This is due to stronger construction and the fact that diesel fuel is a better lubricant than gasoline. This means that the fuel is less likely to remove the desired film of oil on the cylinder walls and piston rings of the

engine. Diesel engines are also better suited for moving heavy loads at low speeds.

Disadvantages

The primary disadvantages of using diesel engines in passenger cars and light trucks include:

- Low power output
- Difficult cold weather starting
- Noise
- Exhaust emissions

Many diesel engines are fit with a turbocharger to increase their power. Combining turbochargers with common rail injection systems have resulted in more horsepower.

In cold weather, diesel engines can be difficult to start because the cold air cannot become hot enough to cause combustion, in spite of the high compression ratios. This problem is compounded by the fact that the cold metal of the cylinder block and head absorbs the heat generated during the compression stroke. Some diesel engines use **glow plugs** to help ignite fuel during cold starting. These small electrical heaters are placed inside the cylinder and are used only to warm the combustion chamber when the engine is cold. Other diesels have a resistive grid heater in the intake manifold to warm the air until the engine reaches operating temperature.

A characteristic of a diesel engine is its sound. This noise, knock or clatter, is caused by the sudden ignition of the fuel as it is injected into the combustion chamber. Through the use of electronically controlled common rail injector systems, manufacturers have been able to minimize the noise.

Emissions have always been an obstacle for diesel cars and new stricter emissions standards will go into effect shortly. Cleaner, low-sulfur, diesel fuel has been available in the United States since 2007. With new technologies and the cleaner fuel, the emissions levels from a diesel engine should be able to run as clean as most gasoline engines. Many diesel vehicles have an assortment of traps and filters to clean the exhaust before it enters the atmosphere. Some diesel engines have diesel particulate filters and catalytic converters (**Figure 9-28**). Particulate filters catch the black soot (unburned carbon compounds) that is typically expelled from a diesel vehicle's exhaust. Most diesel cars will have **selective catalytic reduction** (SCR) systems to reduce NO_x emissions. SCR is a process wherein a substance is injected into the exhaust stream and then absorbed onto a catalyst. This action breaks down the exhaust's NO_x to form H₂O and N₂. Others will use NO_x traps. Diesel engines produce

Figure 9-28 A catalytic converter and particulate trap for a diesel engine. Courtesy of BMW of North America, LLC

very little carbon monoxide because they run with an abundance of air.

OTHER AUTOMOTIVE POWER PLANTS

In an attempt to reduce fuel consumption and harmful exhaust emissions, many manufacturers are supplementing or modifying the basic internal combustion engine. Many of these power plants were developed during the early days of automobiles. Due to the advancements made in electronic controls, they are becoming a viable alternative to the conventional gasoline engine.

Hybrids

A hybrid vehicle has at least two different types of power or propulsion systems. Today's hybrid vehicles have an internal combustion engine and an electric motor (some vehicles have more than one electric motor). A hybrid's electric motor is powered by batteries and/or ultracapacitors, which are recharged by a generator that is driven by the engine (**Figure 9-29**). They are also recharged through regenerative braking. The engine may use gasoline, diesel, or an alternative fuel. Complex electronic controls monitor the operation of the vehicle. Based on the current operating conditions, electronics control the engine, electric motor, and generator.

Depending on the design of the hybrid vehicle, the engine may power the vehicle, assist the electric motor while it is propelling the vehicle, or drive a generator to charge the vehicle's batteries. The electric motor may propel the vehicle by itself, assist the engine while it is propelling the vehicle, or act as a

Figure 9-29 The Honda Civic Hybrid has a 1.3-liter gasoline engine and a 20-horsepower electric motor. Courtesy of American Honda Motor Co., Inc.

generator to charge the batteries. Many hybrids rely exclusively on the electric motor(s) during slow-speed operation, on the engine at higher speeds, and on both during some certain driving conditions.

Often hybrids are categorized as series or parallel designs. In a series hybrid, the engine never directly powers the vehicle. Rather it drives a generator, and the generator either charges the batteries or directly powers the electric motor that drives the wheels (**Figure 9-30**). Currently there are no true series hybrids manufactured. A parallel hybrid vehicle uses either the electric motor or the gas engine to propel the vehicle, or both (**Figure 9-31**). Most current hybrids can be considered as having a series/parallel configuration because they have the features of both designs.

Although most current hybrids are focused on fuel economy, the same construction is used to create high-performance vehicles. The added power of the electric motor boosts the performance levels provided by the engine. Hybrid technology also enhances off-the-road performance. By using individual motors at the front and rear drive axles, additional power can be applied to certain drive wheels when needed.

The engines used in hybrids are specially designed for fuel economy and low emissions. The engines tend to be small displacement engines that use variable valve timing and the Atkinson cycle to

Figure 9-30 The configuration of a series hybrid vehicle.

Figure 9-31 The configuration of a parallel hybrid vehicle.

provide low fuel consumption. These advanced engines, however, cannot produce the power needed for reasonable acceleration by themselves. The electric motor provides additional power for acceleration and for overcoming loads.

Battery-Operated Electric Vehicles A battery-operated electric vehicle, sometimes referred to as an EV, uses one or more electric motors to turn its drive wheels. The electricity for the motors is stored in batteries that must be recharged by an external electrical power source. Normally they are recharged by plugging them into an outlet at home or other locations. The recharging time varies with the type of charger, the size and type of battery, and other factors. Normal recharge time is 4 to 8 hours.

An electric motor is quiet and has few moving parts. It starts well in the cold, is simple to maintain, and does not burn petroleum products to run. The disadvantages of an EV are limited speed, power, and range as well as the need for heavy, costly batteries. However, an EV is much more efficient than a conventional gasoline-fueled vehicle. EVs are considered zero emissions vehicles because they do not directly

pollute the air. The only pollution associated with them is the result of creating the electricity to charge their batteries.

In the early days of the automobile, electric cars outnumbered gasoline cars. Today, there are few EVs on the road but they are commonly used in manufacturing, shipping, and other industrial plants, where the exhaust of an internal combustion engine could cause illness or discomfort to the workers in the area. They are also used on golf courses, where the quiet operation adds to the relaxing atmosphere. Some auto manufacturers are still studying their use. Whether battery-operated EVs return to the market really depends on the development of new batteries and motors. To be practical, EVs need to have much longer driving ranges between recharges and must be able to sustain highway speeds for great distances.

Fuel Cell Electric Vehicles Although just experimental at this time, there is much promise for fuel cell EVs. These vehicles are powered solely by electric motors, but the energy for the motors is produced by fuel cells. Fuel cells rely on hydrogen to produce the electricity. A fuel cell generates electrical power through a chemical reaction. A fuel cell EV uses the electricity produced by the fuel cell to power motors that drive the vehicle's wheels (**Figure 9-32**). The batteries in these vehicles do not need to be charged by an external source.

Fuel cells convert chemical energy to electrical energy by combining hydrogen with oxygen. The hydrogen can be supplied directly as pure hydrogen gas or through a "fuel reformer" that pulls hydrogen from hydrocarbon fuels such as methanol, natural gas, or gasoline. Simply put, a fuel cell is comprised of two electrodes (the anode and the cathode) located on either side of an electrolyte. As the hydrogen enters the fuel cell, the hydrogen atoms give up electrons at the anode and become hydrogen ions in the electrolyte. The electrons that were released at the anode move through an external circuit to the

Figure 9-32 The sources of power for a fuel cell electric vehicle: fuel cell stack (left), power control unit (center), and lithium ion battery pack (right). Courtesy of American Honda Motor Co., Inc.

cathode. As the electrons move toward the cathode, they can be diverted and used to power the vehicle. When the electrons and hydrogen ions combine with oxygen molecules at the cathode, water and heat are formed. There are no smog-producing or greenhouse gases produced. Although vehicles equipped with reformers emit some pollutants, those that run on pure hydrogen are true zero-emission vehicles.

Rotary Engines

The **rotary** engine, or **Wankel** engine, is somewhat similar to the standard piston engine in that it is a spark ignition, internal combustion engine. Its design, however, is quite different. For one thing, the rotary engine uses a rotating motion rather than a reciprocating motion. In addition, it uses ports rather than valves for controlling the intake of the air-fuel mixture and the exhaust of the combusted charge.

The main part of a rotary engine is a roughly triangular rotor that rotates within an oval-shaped housing. The rotor has three convex faces and each face has a recess in it. These recesses increase the overall displacement of the engine. The tips of the rotor are always in contact with the walls of the housing as the rotor moves to seal the sides (chambers) to the walls. As the rotor rotates, it creates three separate chambers of gas. Also, as it rotates, the volume between the sides of the rotor and the housing continuously changes. During rotor rotation, the volume of the gas in each chamber alternately expands and contracts. It is how a rotary engine rotates through the basic four-stroke cycle.

The rotor “walks” around a rigidly mounted gear in the housing. The rotor is connected to the crankshaft through additional gears that allow every rotation of the rotor to rotate the crankshaft three times. This means that the output shaft only rotates three times for every revolution of the rotor, which allows only one power stroke for each revolution of the output shaft. This is why a rotary engine produces less power than a conventional four-stroke engine. When more than one rotor is fitted inside the engine, each rotor is out of phase with the others and the power output is increased.

Referring to **Figure 9-33**, when the side of the rotor is in position “A,” the intake port is uncovered and the air-fuel mixture is entering the upper chamber. As the rotor moves to “B,” the intake port closes and the upper chamber reaches its maximum volume. When full compression has reached “C,” the two spark plugs fire, one after the other, to start the power stroke. At “D,” the side of the rotor uncovers the exhaust port and exhaust begins. This

Figure 9-33 A rotary engine cycle.

cycle continues until the rotor returns to “A” and the intake cycle starts once again.

The rotating combustion chamber engine is small and light for the amount of power it produces, which makes it attractive for use in automobiles. However, the rotary engine at present cannot compete with a piston gasoline engine in terms of durability, exhaust emissions, and economy. After a few years of not offering a rotary engine, Mazda has released a version of the engine, called the Renesis, that produces lower emissions and has two rotors.

Stratified Charge Engines

The stratified charge engine (**Figure 9-34**) combines the features of gasoline and diesel engines. It differs

Figure 9-34 A typical stratified charge engine.

from the conventional gasoline engine in that the air-fuel mixture is deliberately stratified to produce a small rich mixture at the spark plug while providing a leaner, more efficient and cleaner burning main mixture. In addition, the air-fuel mixture is swirled to provide for more complete combustion.

A large amount of very lean mixture is drawn through the main intake valve on the intake stroke to the main combustion chamber. At the same time, a small amount of rich mixture is drawn through the auxiliary intake valve into the precombustion chamber. At the end of the compression stroke, the spark plug fires the rich mixture in the precombustion chamber. As the rich mixture ignites, it in turn ignites the lean mixture in the main chamber. The lean mixture minimizes the formation of carbon monoxide during the power stroke. In addition, the peak temperature stays low enough to minimize the formation of NO_x , and the mean temperature is held high enough and long enough to reduce hydrocarbon emissions.

The Honda CVCC engine uses a stratified charge design. This engine uses a third valve to release the initial charge. The stratified charge combustion chamber has three important advantages: It produces good part-load fuel economy, it can run efficiently on low-octane fuel, and it has low exhaust emissions.

Homogeneous Charge Compression Ignition Engines

Within the next few years, some automobiles will be equipped with **homogeneous charge compression ignition (HCCI)** engines. HCCI engines offer the high efficiency and torque of a diesel engine while providing the low emissions and power of a gasoline engine. Basically these engines have a combustion process that allows a gasoline or diesel engine to operate with either compression ignition or spark ignition. With spark ignition the air and fuel are mixed (homogenized) before ignition and ignition is caused by a spark. In a diesel engine the air and fuel are never mixed. The air is compressed and ignition occurs when fuel is sprayed into the high-temperature air. In an HCCI engine, the air and fuel are mixed and ignition occurs as the mixture is compressed. During compression, the mixture gets hot enough to “autoignite.” HCCI is also referred to as controlled auto-ignition (CAI).

In an HCCI engine, combustion immediately and simultaneously begins at several points within the mixture. This means the combustion process occurs rapidly and is controlled by the quality and temperature of the compressed mixture. This spontaneous

combustion produces a flameless release of energy to drive the piston down.

The HCCI engine runs on a lean, diluted mixture of fuel, air, and exhaust gases. Only the heat inside the cylinder determines when ignition will occur. This fact makes it hard to control ignition timing. The temperature of the mixture at the beginning of the compression stroke must be increased to autoignition temperatures at the end of the compression stroke. Autoignition usually occurs when the temperature reaches 1,430°F to 1,520°F (777°C to 827°C) for gasoline. The engine's control unit must supply the correct amount of fuel mixed with the correct amount of air in order for combustion to occur at the right time. In addition, the control unit must provide a mixture that is hot enough to be able to autoignite at the end of the compression stroke. Therefore, it must be able to vary the compression ratio, the temperature of the intake air, the pressure of the intake air, or the amount of retained or reinducted exhaust gas. The role of the control unit is extremely important for proper operation.

Dual Mode A practical application of an HCCI engine would be one with dual mode capabilities. The spark ignition mode could be used when high power is required, and the compression ignition mode would be used during steady loads and speeds. To do this, the engine must be able to smoothly switch from the HCCI mode to the spark ignition mode from one cylinder firing to the next. This would require precise control of valve timing, air and fuel metering, and spark plug timing.

Benefits A gasoline HCCI engine could deliver almost the same fuel economy as a diesel engine and at a much lower cost. GM estimates that HCCI could improve gasoline engine fuel efficiency by 20%, while emitting near-zero amounts of NO_x and particulate matter. In fact, HCCI engines emit extremely low levels of NO_x without a catalytic converter.

However, a gasoline engine running in the HCCI mode produces more noise and vibrations than a conventional engine. Also, they tend to experience incomplete combustion, which leads to hydrocarbon and carbon monoxide emissions. To rectify this, HCCI engines are fitted with typical emission control systems, including an oxidizing catalytic converter.

Variable Compression Ratio Engines

Variable compression engines are being explored, not only for use with HCCI, but for use in conventional engines. Changing the compression ratio is

Figure 9-35 The SVC can vary the engine's compression ratio from 8:1 to 14:1.
Courtesy of Saab Automobile AB

one way to provide power when needed and minimizing fuel consumption. One way to do this is through changes in valve timing. The process is similar to the modifications made for the Atkinson cycle. Another way is to change the volume of the combustion chamber in response to the engine's operating conditions.

Saab has developed such an engine, called Saab variable compression (SVC), that has a cylinder head constructed with integrated cylinders. The compression ratio is altered by changing the slope of the cylinder head in relation to the engine block. This changes the volume of the combustion chamber (**Figure 9-35**). The cylinder head is pivoted at the crankshaft by a hydraulic actuator and can be as much as 4 degrees. The engine management system adjusts the angle in response to engine speed, engine load, and fuel quality. The cylinder head is sealed to the engine block by a rubber bellows.

ENGINE IDENTIFICATION

USING SERVICE INFORMATION

Normally, information used to identify the size of an engine is given in service manuals at the beginning of the section covering that particular manufacturer.

By referring to the VIN, much information about the vehicle can be determined. Identification numbers are also found on the engine. Some manufacturers use tags or stickers attached at various places, such as the valve cover or oil pan. Blocks often have a serial number stamped into them (**Figure 9-36**). Service manuals typically give the location of the code for a particular engine. The engine code is generally found beside the serial number. A typical

Figure 9-36 Examples of the various identification numbers found on an engine.

engine code might be DZ or MO. These letters indicate the horsepower rating of the engine, whether it was built for an automatic or manual transmission, and other important details. The engine code will help you determine the correct specifications for that particular engine.

Chapter 7 for instructions on how to decipher a VIN.

Engine ID Tags Many engines have ID tags or stickers attached to various places on the engine, such as the valve cover or oil pan. The tags include the displacement, assembly plant, model year, change level, engine code, and date of production. Service manuals normally note the location of these stickers or tags on a particular engine.

Casting Numbers Whenever an engine part such as an engine block or head is cast, a number is put into the mold to identify the casting and the date when the part was made. This date does not indicate when the engine was assembled or placed into the vehicle at the factory. A part made during one year may be installed in the vehicle in the following year; therefore, the casting date may not match the model year of the vehicle. Casting numbers should not be used for identifying the displacement of an engine. They only indicate the basic design of an engine. The same block or head can be used with a variety of different displacement engines.

Underhood Label Vehicles produced since 1972 have an underhood emission control label that contains such useful information as ignition timing specifications, emission control devices, engine size, vacuum hose routing, and valve adjustment specifications.

ENGINE DIAGNOSTICS

As the trend toward the integration of ignition, fuel, and emission systems progresses, diagnostic test equipment must also keep up with these changes. New tools and techniques are constantly being developed to diagnose electronic engine control systems. However, not all engine performance problems are related to electronic control systems; therefore, technicians still need to understand basic engine

tests. These tests are an important part of modern engine diagnosis.

Compression Test

Internal combustion engines depend on compression of the air-fuel mixture to maximize the power produced by the engine. The upward movement of the piston on the compression stroke compresses the air-fuel mixture within the combustion chamber. The air-fuel mixture gets hotter as it is compressed. The hot mixture is easier to ignite, and when ignited it generates much more power than the same mixture at a lower temperature.

If the combustion chamber leaks, some of the air-fuel mixture will escape when it is compressed, resulting in a loss of power and a waste of fuel. The leaks can be caused by burned valves, a blown head gasket, worn rings, slipped timing belt or chain, worn valve seats, a cracked head, and more.

An engine with poor compression (lower compression pressure due to leaks in the cylinder) will not run correctly. If a symptom suggests that the cause of a problem may be poor compression, a compression test is performed.

A compression gauge is used to check cylinder compression. The dial face on the typical compression gauge indicates pressure in both pounds per square inch (psi) and metric kilopascals (kPa). Most compression gauges have a vent valve that holds the highest pressure reading on its meter. Opening the valve releases the pressure when the test is complete. The steps for conducting a cylinder compression test are shown in Photo Sequence 6.

Ford, Toyota, and other hybrids use Atkinson cycle engines. These engines delay the closing of the intake valve, which means that the overall compression ratio and displacement of the engine are reduced. Therefore, when conducting a compression test on these engines, expect a slightly lower reading than what you would expect from a conventional engine.

To conduct a compression test on a Ford Escape, you must use a scan tool and the one from Ford is preferred. The scan tool allows you to enter into the engine cranking diagnostic mode. This mode allows the engine to crank with the fuel injection system disabled. It also makes sure that the starter motor/generator is not activated (except for activating the starter motor to crank the engine), which not only is good for safety purposes, it is also good because the load of the generator cannot affect the test results because it is not energized. Always follow the sequence as stated in the service manual. Failure to do so will result in bad readings.

Conducting a Cylinder Compression Test

P6-1 Before conducting a compression test, disable the ignition and the fuel injection system. Most manufacturers recommend that the engine be warm when testing.

P6-2 Prop the throttle plate into a wide-open position to allow an unrestricted amount of air to enter the cylinders during the test.

P6-3 Remove all of the engine's spark plugs.

P6-4 Connect a remote starter button to the starter system.

P6-5 Many types of compression gauges are available. The screw-in type tends to be the most accurate and easiest to use.

P6-6 Carefully install the gauge into the spark plug hole of the first cylinder.

P6-7 Connect a battery charger to the car to allow the engine to crank at consistent and normal speeds needed for accurate test results.

P6-8 Depress the remote starter button and observe the gauge's reading after the first engine revolution.

P6-9 Allow the engine to turn through four revolutions, and observe the reading after the fourth. The reading should increase with each revolution.

Conducting a Cylinder Compression Test *(continued)*

P6-10 Readings observed should be recorded. After all cylinders have been tested, a comparison of cylinders can be made.

P6-13 After completing the test on all cylinders, compare them. If one or more cylinders is much lower than the others, continue testing those cylinders with the wet test.

P6-11 Before removing the gauge from the cylinder, release the pressure from it using the release valve on the gauge.

P6-12 Each cylinder should be tested in the same way.

P6-14 Squirt a small amount of oil into the weak cylinder(s).

P6-15 Reinstall the compression gauge into that cylinder and conduct the test.

P6-16 If the reading increases with the presence of oil in the cylinder, the most likely cause of the original low readings was poor piston ring sealing. Using oil during a compression test is normally referred to as a wet test.

Wet Compression Test Because many things can cause low compression, it is advisable to conduct a wet compression test on the low cylinders. This test allows you to identify if it is caused by worn or damaged piston rings. To conduct this test, add two squirts of oil into the low cylinders. Then measure the compression of that cylinder. If the readings are higher, it is very likely that the piston rings are the cause of the problem. The oil temporarily seals the piston to the cylinder walls, which is why the readings increased. If the readings do not increase, or increase only slightly, the cause of the low readings is probably the valves.

Cylinder Leakage Test

If a compression test shows that any of the cylinders are leaking, a cylinder leakage test can be performed to measure the percentage of compression lost and to help locate the source of leakage. A cylinder leakage tester applies compressed air to a cylinder through the spark plug hole. The source of the compressed air is normally the shop's compressed air system. The tester's pressure regulator controls the pressure applied to the cylinder. A gauge registers the percentage of air pressure lost when the compressed air is applied to the cylinder. The scale on the gauge typically reads 0% to 100%. The amount and location of the air that escapes give a good idea of the engine's condition and can pinpoint where compression is lost.

PROCEDURE

1. Make sure the engine is at operating condition.
2. Remove the radiator cap, oil filler cap, dipstick tube, air filter cover, and all spark plugs.
3. Rotate the crankshaft with a remote starter button so that the piston of the tested cylinder is at TDC on its compression stroke (**Figure 9-37**). This ensures that the valves of that cylinder are closed.
4. Insert the threaded adapter on the end of the tester's air pressure hose into the spark plug hole.
5. Allow the compressed air to enter the cylinder.
6. Observe the gauge reading (**Figure 9-38**).
7. Listen and feel to identify the source of any escaping air.

A zero reading means there is no leakage in the cylinder. Readings of 100% indicate that the cylinder will not hold any pressure. Any reading that is more than 0% indicates there is some leakage (**Figure 9-39**). Most engines, even new ones, experience some leakage

Figure 9-37 Rotate the engine so that the piston of the cylinder that will be tested is at TDC before checking leakage.

CAUTION!

Always follow the precautions given by the manufacturer when conducting a compression test or other engine-related tests, especially when doing this on a hybrid vehicle. In most hybrids, the engine is cranked by a high-voltage motor. Because this motor is required to run the test, the high-voltage system cannot be isolated. Therefore, extreme care must be taken and all appropriate safety precautions must be followed.

Figure 9-38 The reading on the tester is the percentage of air that leaked out during the test.

Measured Leakage Conclusion	
Less than 10%	Good
Between 10 and 20%	Acceptable
Between 20 and 30%	Worn engine
Above 30%	Definite problem
100%	Serious problem

Figure 9-39 Cylinder leakage test results.

around the rings. Up to 20% is considered acceptable. When the engine is running, the rings will seal much better and the actual leakage will be lower.

SHOP TALK

Some leakage testers read in the opposite way; a reading of 100% may indicate a totally sealed cylinder, whereas 0% indicates a very serious leak. Always refer to the manufacturer's literature before using test equipment.

The location of the compression leak can be found by listening and feeling around various parts of the engine (**Figure 9-40**).

Cylinder Power Balance Test

The cylinder power balance test is used to check if all of the engine's cylinders are producing the same amount of power. Ideally, all cylinders will produce the same amount. To check an engine's power balance, each cylinder is disabled, one at a time, and the change in engine speed is recorded. If all of the cylinders are producing the same amount of power, engine speed will drop the same amount as each cylinder is disabled. Unequal cylinder power balance can be caused by the following problems:

- Defective ignition coil
- Defective spark plug wire
- Defective or worn spark plug

Source of Leakage	Probable Cause
Radiator	Faulty head gasket Cracked cylinder head Cracked engine block
Throttle body	Damaged intake valve
Tailpipe	Damaged exhaust valve
Oil filler or dipstick tube	Worn piston rings
Adjacent spark plug hole	Faulty head gasket Cracked cylinder head

Figure 9-40 Sources of cylinder leakage and the probable causes.

- Damaged head gasket
- Worn piston rings
- Damaged piston
- Damaged or burned valves
- Broken valve spring
- Worn camshaft
- Defective lifters, pushrods, and/or rocker arms
- Leaking intake manifold
- Faulty fuel injector

A power balance test is performed quickly and easily using an engine analyzer, because the firing of the spark plugs can be automatically controlled or manually controlled by pushing a button. Some vehicles have a power balance test built into the engine control computer. This test is either part of a routine self-diagnostic mode or must be activated by the technician.

WARNING!

On some computer-controlled engines, certain components must be disconnected before attempting the power balance test. Because of the wide variations from manufacturer to manufacturer, always check the appropriate service manual. On all vehicles with an electric cooling fan, override the controls by using jumper wires to make the fan run constantly. If the fan control cannot be bypassed, disconnect the fan. Be careful not to run the engine with a disabled cylinder for more than 15 seconds. The unburned fuel in the exhaust can build up in the catalytic converter and create an unsafe situation. Also run the engine for at least 10 seconds between testing individual cylinders.

Connect the engine analyzer's leads according to the manufacturer's instructions. Turn the engine on and allow it to reach normal operating temperature. Set the engine speed at 1,000 rpm and connect a vacuum gauge to the intake manifold. As each cylinder is shorted, note and record the rpm drop and the change in vacuum.

As each cylinder is shorted, a noticeable drop in engine speed should be noted. Little or no decrease in speed indicates a weak cylinder. If all of the readings are fairly close to each other, the engine is in good condition. If the readings from one or more cylinders differ from the rest, there is a problem. Further testing

Figure 9-41 The vacuum gauge is connected to the intake manifold where it reads engine vacuum.

may be required to identify the exact cause of the problem.

Vacuum Tests

Measuring intake manifold vacuum is another way to diagnose the condition of an engine. Vacuum is formed by the downward movement of the pistons during their intake stroke. If the cylinder is sealed, a maximum amount will be formed.

Manifold vacuum is tested with a vacuum gauge. The gauge's hose is connected to a vacuum fitting on the intake manifold (**Figure 9-41**). Normally a "tee" fitting and short piece of vacuum hose are used to connect the gauge.

Vacuum gauge readings (**Figure 9-42**) can be interpreted to identify many engine conditions,

including the ability of the cylinder to seal, the timing of the opening and closing of the engine's valves, and ignition timing.

Ideally each cylinder of an engine will produce the same amount of vacuum; therefore, the vacuum gauge reading should be steady and give a reading of at least 17 inches of mercury (in. Hg). If one or more cylinders produce more or less vacuum than the others, the needle of the gauge will fluctuate. The intensity of the fluctuation indicates the severity of the problem. For example, if the reading on the vacuum gauge fluctuates between 10 and 17 in. Hg we should look at the rhythm of the needle. If the needle seems to stay at 17 most of the time but drops to 10 and quickly rises, we know that the reading is probably caused by a problem in one cylinder. Fluctuating or low readings can indicate many different problems. For example, a low, steady reading might be caused by retarded ignition timing or incorrect valve timing. A sharp vacuum drop at regular intervals might be caused by a burned intake valve. Other conditions that can be revealed by vacuum readings follow:

- Stuck or burned valves
- Improper valve or ignition timing
- Weak valve springs
- Faulty PCV, EGR, or other emission-related system
- Uneven compression
- Worn rings or cylinder walls
- Leaking head gaskets
- Vacuum leaks
- Restricted exhaust system
- Ignition defects

Oil Pressure Testing

An oil pressure test is used to determine the wear of an engine's parts. The oil pressure test is performed with an oil pressure gauge, which measures the pressure of the oil as it circulates through the engine. Basically, the pressure of the oil depends on the efficiency of the oil pump and the clearances through which the oil flows. Excessive clearances, most often caused by wear between a shaft and its bearings, will cause a decrease in oil pressure.

Loss of performance, excessive engine noise, and poor starting can be caused by abnormal oil pressure. When the engine's oil pressure is too low, premature wear of its parts will result.

An oil pressure tester is a gauge with a high-pressure hose attached to it. The scale of the gauge typically reads from 0 to 100 psi (0 to 690 kPa). Using the correct fittings and adapters, the hose is connected to an oil passage in the engine block. The test normally includes the following steps:

1. Remove the oil pressure sensor (**Figure 9-43**) and tighten the threaded end of the gauge's hose into that bore.
2. Run the engine until it reaches normal operating temperature.
3. Observe the gauge reading while the engine is running at about 1,000 rpm and at 2,500 rpm (or the specified engine speed).
4. Compare the readings to the manufacturer's specifications.

Excessive bearing clearances are not the only possible causes for low oil pressure readings; others are oil pump-related problems, a plugged oil pickup screen, weak or broken oil pressure relief valve, low oil level, contaminated oil, or low oil viscosity.

Figure 9-43 The oil pressure gauge is installed into the oil pressure sending unit's bore in the engine block.

Higher than normal readings can be caused by too much oil, cold oil, high oil viscosity, restricted oil passages, and a faulty pressure regulator.

Oil Pressure Warning Lamp The instrument panel of most vehicles has an oil pressure warning lamp that lights when the oil pressure drops below a particular amount. This lamp should turn on when the ignition key is initially turned to the *on* position and the engine is not running. Once the engine starts, the lamp should go out. If the lamp fails to turn off, there may be an oil pressure problem or a fault in the warning lamp electrical circuit. To determine if the problem is the engine, conduct an oil pressure test. If there is normal oil pressure, the cause of the lamp staying on is an electrical problem.

EVALUATING THE ENGINE'S CONDITION

Once the compression, cylinder leakage, vacuum, and power balance tests are performed, a technician is ready to evaluate the engine's condition. For example, an engine with good relative compression but high cylinder leakage past the rings is typical of a high-mileage worn engine. This engine would have these symptoms: excessive blowby, lack of power, poor performance, and reduced fuel economy.

If these same compression and leakage test results are found on an engine with comparatively low mileage, the problem is probably stuck piston rings that are not expanding properly. If this is the case, try treating the engine with a combustion chamber cleaner, oil treatment, or engine flush. If this fails to correct the problem, an engine overhaul is required.

A cylinder that has poor compression but minimal leakage indicates a valve train problem. Under these circumstances, a valve might not be opening at the right time, might not be opening enough, or might not be opening at all. This condition can be confirmed on engines with a pushrod-type valve train by pulling the rocker covers and watching the valves operate while the engine is cycled. If one or more valves fail to move, either the lifters are collapsed or the cam lobes are worn. If all of the cylinders have low compression with minimal leakage, the most likely cause is incorrect valve timing.

If compression and leakage are both good, but the power balance test reveals weak cylinders, the cause of the problem is outside the combustion chamber. Assuming there are no ignition or fuel problems, check for broken, bent, or worn valve train components, collapsed lifters, leaking intake manifold, or excessively leaking valve guides. If the latter is suspected,

Figure 9-44 Oil leaking from around the oil pan gasket.

squirt some oil on the guides. If they are leaking, blue smoke will be seen in the exhaust.

Fluid Leaks

When inspecting the engine, check it for leaks (**Figure 9-44**). There are many different fluids under the hood of an automobile so care must be taken to identify the type of fluid that is leaking (**Figure 9-45**). Carefully look at the top and sides of the engine, and note any wet residue that may be present. Sometimes road dirt will mix with the leaking fluid and create a heavy coating. Also look under the vehicle for signs of leaks or drips; make sure you have good lighting. Note the areas around the leaks and identify the possible causes. Methods for positively identifying the source of leaks from various components are covered later in

Description	Probable Source
Honey or dark greasy fluid	Engine oil
Honey or dark thick fluid with a chestnut smell	Gear oil
Green, sticky fluid	Engine coolant
Slippery clear or yellowish fluid	Brake fluid
Slippery red fluid	Transmission or power-steering fluid
Bluish watery fluid	Washer fluid

Figure 9-45 Identification of fluid leaks.

this section. All leaks should be corrected because they can result in more serious problems.

Sometimes smell will identify the fluid. Gasoline evaporates when it leaks out and may not leave any residue, but it is easy to identify by its smell.

Exhaust Smoke Diagnosis

Examining and interpreting the vehicle’s exhaust can give clues of potential engine problems. Basically there should be no visible smoke coming out of the tailpipe. There is an exception to this rule, however, on a cold day after the vehicle has been idling for awhile, it is normal for white smoke to come out of the tailpipe. This is nothing else but the water that has condensed in the exhaust system becoming steam. However, the steam should stop once the engine reaches normal operating temperature. If it does not, a problem is indicated. The color of the exhaust is used to diagnose engine concerns (**Figure 9-46**).

Engine Type	Visible Sign	Diagnosis	Probable Causes
Gasoline	Gray or black smoke	Incomplete combustion or excessively rich A/F mixture	■ Clogged air filter ■ Faulty fuel injection system ■ Faulty emission control system ■ Ignition problem ■ Restricted intake manifold
Diesel	Gray or black smoke	Incomplete combustion	■ Clogged air filter ■ Faulty fuel injection system ■ Faulty emission control system ■ Wrong grade of fuel ■ Engine overheating
Gasoline and Diesel	Blue smoke	Burning engine oil	■ Oil leaking into combustion chamber ■ Worn piston rings, cylinder walls, valve guides, or valve stem seals ■ Oil level too high
Gasoline	White smoke	Coolant/water is burning in the combustion chamber	■ Leaking head gasket ■ Cracked cylinder head or block
Diesel	White smoke	Fuel is not burning	■ Faulty injection system ■ Engine overheating

Figure 9-46 Exhaust analysis.

NOISE DIAGNOSIS

More often than not, malfunction in the engine will reveal itself first as an unusual noise. This can happen before the problem affects the driveability of the vehicle. Problems such as loose pistons, badly worn rings or ring lands, loose piston pins, worn main bearings and connecting rod bearings, loose vibration damper or flywheel, and worn or loose valve train components all produce telltale sounds. Unless the technician has experience in listening to and interpreting engine noises, it can be very hard to distinguish one from the other.

Customer Care

When attempting to diagnose the cause of abnormal engine noise, it may be necessary to temper the enthusiasm of a customer who thinks they have pinpointed the exact cause of the noise using nothing more than their own two ears. While the owner's description may be helpful (and should always be asked for), it must be stressed that one person's "rattle" can be another person's "thump." You are the professional. The final diagnosis is up to you. If customers have been proved correct in their diagnosis, make it a point to tell them so. Everyone feels better about dealing with an automotive technician who listens to them.

When correctly interpreted, engine noise can be a very valuable diagnostic aid. For one thing, a costly and time-consuming engine teardown might be avoided. Always make a noise analysis before doing any repair work. This way, there is a much greater likelihood that only the necessary repair procedures will be done.

Using a Stethoscope

Some engine sounds can be easily heard without using a listening device, but others are impossible to hear unless amplified. A stethoscope (**Figure 9-47**) is very helpful in locating engine noise by amplifying the sound waves. It can also distinguish between normal and abnormal noise. The procedure for using a stethoscope is simple. Use the metal prod to trace the sound until it reaches its maximum intensity. Once the precise location has been discovered, the sound can be better evaluated. A sounding stick, which is nothing more than a long, hollow tube, works on the same principle, though a stethoscope gives much clearer results.

Figure 9-47 Using a stethoscope helps to identify the source of an abnormal noise.

The best results, however, are obtained with an electronic listening device. With this tool you can tune into the noise. Doing this allows you to eliminate all other noises that might distract or mislead you.

WARNING!

Be very careful when listening for noises around moving belts and pulleys at the front of the engine. Keep the end of the hose or stethoscope probe away from the moving parts. Physical injury can result if the hose or stethoscope is pulled inward or flung outward by moving parts.

Common Noises

Figure 9-48 gives examples of abnormal engine noises, including a description of the sound, and their likely causes. An important point to keep in mind is that insufficient lubrication is the most common cause of engine noise. For this reason, always check the fluid levels first before moving on to other areas of the vehicle. Some noises are more pronounced on a cold engine because clearances are greater when parts are not expanded by heat. Remember that aluminum and iron expand at different rates as temperatures rise. For example, a knock that disappears as the engine warms up probably is piston slap or knock. An aluminum piston expands more than the iron block, allowing the piston to fit more closely as engine temperature rises.

Also keep in mind that loose accessories, cracked flexplates, loose bolts, bad belts, broken mechanical fuel pump springs, and other noninternal engine problems can be mistaken for more serious internal

Type	Sound	Mostly Heard During	Possible Causes
Ring noise	High-pitched rattle or clicking	Acceleration	<ul style="list-style-type: none"> ■ Worn piston rings ■ Worn cylinder walls ■ Broken piston ring lands ■ Insufficient ring tension
Piston slap	Hollow, bell-like	Cold engine operation and is louder during acceleration	<ul style="list-style-type: none"> ■ Worn piston rings ■ Worn cylinder walls ■ Collapsed piston skirts ■ Misaligned connecting rods ■ Worn bearings ■ Excessive piston to wall clearance ■ Poor lubrication
Piston pin knock	Sharp, metallic rap	Hot engine operation at idle	<ul style="list-style-type: none"> ■ Worn piston pin ■ Worn piston pin boss ■ Worn piston pin bushing ■ Lack of lubrication
Main bearing noise	Dull, steady knock	Louder during acceleration	<ul style="list-style-type: none"> ■ Worn bearings ■ Worn crankshaft
Rod bearing noise	Light tap to heavy knocking or pounding	Idle speeds and low load higher speeds	<ul style="list-style-type: none"> ■ Worn bearings ■ Worn crankshaft ■ Misaligned connecting rod ■ Lack of lubrication
Thrust bearing noise	Heavy thumping	Irregular sound, may be heard only during acceleration	<ul style="list-style-type: none"> ■ Worn thrust bearing ■ Worn crankshaft ■ Worn engine saddles
Tappet noise	Light regular clicking	Mostly heard during idle	<ul style="list-style-type: none"> ■ Improper valve adjustment ■ Worn or damaged valve train ■ Dirty hydraulic lifters ■ Lack of lubrication
Timing chain noise	Severe knocking	Increases with increase in engine speed	<ul style="list-style-type: none"> ■ Loose timing chain

Figure 9-48 Common engine noises.

engine problems. Always attempt to identify the exact source before completing your diagnosis. In most cases, the source of internal engine noises is best identified by tearing down the engine and inspecting all parts.

Abnormal Combustion Noises

Detonation and preignition noises are caused by abnormal engine combustion. **Detonation** knock or **ping** is a noise most noticeable during acceleration with the engine under load and running at normal temperature. Detonation occurs when part of the air-fuel mixture begins to ignite on its own. This results in the collision of two flame fronts (**Figure 9-49**). One flame front is the normal front moving from the spark plug tip. The other front begins

at another point in the combustion chamber. The air-fuel mixture at that point is ignited by heat, not by the spark. The colliding flame fronts cause high-frequency shock waves (heard as a knocking or pinging sound) that could cause physical damage to the pistons, valves, bearings, and spark plugs. Excessive detonation can be very harmful to the engine.

Detonation is usually caused by excessively advanced ignition timing, engine overheating, excessively lean mixtures, or the use of gasoline with too low of an octane rating. A malfunctioning EGR valve can also cause detonation and even rod knock.

Another condition that also causes pinging or spark knocking is called **preignition**, which occurs when combustion begins before the spark plug fires

Figure 9-49 Detonation. Courtesy of Federal-Mogul Corporation

Figure 9-50 Preignition. Courtesy of Federal-Mogul Corporation

(Figure 9-50). Any hot spot within the combustion chamber can cause preignition. Common causes of preignition are incandescent carbon deposits in the combustion chamber, a faulty cooling system, too hot of a spark plug, poor engine lubrication, and cross firing. Preignition can lead to detonation; however, preignition and detonation are two separate events. Preignition normally does not cause engine damage; detonation does.

Sometimes abnormal combustion causes engine parts to make an abnormal noise. For example, *rumble* is a term that is used to describe the knock or noise resulting from abnormal ignition. Rumble is a vibration of the crankshaft and connecting rods that is caused by multisurface ignition. This is a form of preignition in which several flame fronts occur simultaneously from overheated deposit particles.

Multisurface ignition causes a tremendous sudden pressure rise near TDC. It has been reported that the rate of pressure rise during rumble is five times the rate of normal combustion.

Cleaning Carbon Deposits A buildup of carbon on the top of the piston, intake valve, or in the combustion chamber can cause a number of driveability concerns, including preignition. There are a number of

techniques used to remove or reduce the amount of carbon inside the engine. One way, of course, is to disassemble the engine and remove the carbon with a scraper or wire wheel. Two other methods are more commonly used. One is simply adding chemicals to the fuel. These chemicals work slowly so do not expect quick results.

The other method requires more labor but is more immediately effective. This uses a carbon blaster, which is a machine that uses compressed air to force crushed walnut shells into the cylinders. The shells beat on the piston top and combustion chamber walls to loosen and remove the carbon. Basically to use a carbon blaster, the intake manifold and spark plugs are removed. The output hose of the blaster is attached to a cylinder's intake port or inserted into the bore for the fuel injector. A hose is inserted into the spark plug bore; this is where the shells and carbon exit the cylinder. Once connected to the cylinder, the blaster forces a small amount of shells in and out of the cylinder. Hopefully, the carbon deposits leave with the shells. To help remove any remaining bits of shells, compressed air is applied to the cylinder. This operation is done at each cylinder. It is important to note that any remaining shell bits will be burned once the engine is run again.

CASE STUDY

A customer complains that the engine has a rough idle and does not have as much power as it used to. The customer also says that the engine is difficult to start when it is cold and runs better while cruising at highway speeds. On examining the car, it is found that it has a four-cylinder engine with nearly 65,000 miles on it. Driving the car verifies the customer's complaint.

Diagnosis begins with a visual inspection that reveals only that the car has been well maintained. Because there is an endless list of possible causes for these problems, the first test is for engine vacuum. With the vacuum gauge connected to the manifold and the engine at idle speed, the gauge's needle constantly drops from a normal reading to 10 in. Hg. The rhythm of the drop matches the rhythm of the idle. The behavior of the gauge indicates a probable problem in one cylinder.

To verify this diagnosis, a cylinder power balance test is conducted. The results show an engine speed drop of 100 to 125 rpm when cylinders 1, 2, and 4 are shorted, and a drop of only 10 rpm when cylinder 3 is shorted. Based on this test, cylinder 3 is identified as having the problem.

To identify the exact fault, further testing is required. The spark plugs are removed and inspected. All look normal, including the one from cylinder 3. Next, a compression test is taken. All cylinders have normal readings. A cylinder leakage test is then conducted and it too shows normal conditions. The results of the power balance, compression, and cylinder leakage tests lead to the conclusion that the cause has to be in the valve train. Something is preventing a valve from opening.

Removing the cam cover for a visual inspection leads to the discovery of the fault: The intake lobe for cylinder 3 on the camshaft is severely worn. A replacement of the camshaft and matching lifter will correct the problem. The worn lobe only affects the opening of the valve and does not prevent it from sealing, which is why the compression and cylinder leakage test results were normal. Cylinder power and vacuum are affected by the valve not opening fully.

SUMMARY

- Automotive engines are classified by several different design features such as operational cycles, number of cylinders, cylinder arrangement, valve train type, valve arrangement, ignition type, cooling system, and fuel system.
- The basis of automotive gasoline engine operation is the four-stroke cycle. This includes the intake stroke, compression stroke, power stroke, and exhaust stroke. The four strokes require two full crankshaft revolutions.
- The most popular engine designs are the inline (in which all the cylinders are placed in a single row) and V-type (which features two rows of cylinders). The slant design is much like the inline, but the entire block is placed at a slant. Opposed cylinder engines use two rows of cylinders located opposite the crankshaft.
- The two basic valve and camshaft placement configurations currently in use on four-stroke engines are the overhead valve and overhead cam.
- Bore is the diameter of a cylinder, and stroke is the length of piston travel between top dead center (TDC) and bottom dead center (BDC). Together these two measurements determine the displacement of the cylinder.
- Compression ratio is a measure of how much the air and fuel are compressed during the compression stroke.

- In an Atkinson cycle engine the intake valve is held open longer than normal during the compression stroke. As a result, the amount of mixture in the cylinder and the engine's effective displacement and compression ratio are reduced.
 - Diesel engines have compression ignition systems. Rather than relying on a spark for ignition, a diesel engine uses the heat produced by compressing the intake air to ignite the fuel.
 - A hybrid electric vehicle has two different types of power or propulsion systems: an internal combustion engine and an electric motor.
 - A compression test is conducted to check a cylinder's ability to seal and therefore its ability to compress the air-fuel mixture inside the cylinder.
 - A cylinder leakage test is performed to measure the percentage of compression lost and to help locate the source of leakage.
 - A cylinder power balance test reveals whether all of an engine's cylinders are producing the same amount of power.
 - Vacuum gauge readings can be interpreted to identify many engine conditions, including the ability of the engine's cylinders to seal, the timing of the opening and closing of the engine's valves, and ignition timing.
 - An oil pressure test measures the pressure of the engine's oil as it circulates throughout the engine. This test is very important because abnormal oil pressures can cause a host of problems, including poor performance and premature wear.
 - Carefully observing the exhaust can aid engine diagnosis.
 - An engine malfunction often reveals itself as an unusual noise. When correctly interpreted, engine noise can be a very helpful diagnostic aid.
6. Which of the following statements about engines is *not* true?
 - a. The engine provides the rotating power to drive the wheels through the transmission and driving axle.
 - b. Only gasoline engines are classified as internal combustion.
 - c. The combustion chamber is the space between the top of the piston and the cylinder head.
 - d. For the combustion in the cylinder to take place completely and efficiently, air and fuel must be combined in the right proportions.
 7. Which stroke in the four-stroke cycle begins as the compressed fuel mixture is ignited in the combustion chamber?
 - a. power stroke
 - b. exhaust stroke
 - c. intake stroke
 - d. compression stroke
 8. *True or False?* In an HCCI engine, combustion immediately and simultaneously produces a steady flame across the mixture.
 9. Which of the following is *not* a true statement about diesel engines?
 - a. The operation and main components of a diesel engine are comparable to those of a gasoline engine.
 - b. Diesel and gasoline engines are available as four-stroke combustion cycle engines.
 - c. Diesel engines rely on glow plugs instead of spark plugs to initiate ignition.
 - d. The compression ratio of diesel engines is typically three times that of a gasoline engine.
 10. *True or False?* When looking at the front of a running engine, it will be rotating in a counter-clockwise direction.
 11. Which engine system removes burned gases and limits noise produced by the engine?
 - a. exhaust system
 - b. emission control system
 - c. ignition system
 - d. air-fuel system
 12. In a six-cylinder engine with a firing order of 1-4-5-2-3-6, what stroke is piston #5 on when #1 is on its compression stroke?
 13. The stroke of an engine is _____ the crank throw.
 - a. half
 - b. twice
 - c. four times
 - d. equal to

REVIEW QUESTIONS

1. What occurs in the combustion chamber of a four-stroke engine?
2. Name the four strokes of a four-stroke cycle engine.
3. As an engine's compression ratio increases, what should happen to the octane rating of the gasoline?
4. What test can be performed to check the efficiency of individual cylinders?
5. Describe tappet noise.

14. *True or False?* The camshaft for a two-stroke cycle engine is always located in the engine block.
15. Which of the following is an expression of how much of the heat formed during the combustion process is available as power from the engine?
 - a. mechanical efficiency
 - b. engine efficiency
 - c. volumetric efficiency
 - d. thermal efficiency

ASE-STYLE REVIEW QUESTIONS

1. While diagnosing the cause for black smoke from the tailpipe of a gasoline engine: Technician A says that a faulty fuel injection system is a likely cause. Technician B says that it is most likely caused by oil leaking into the combustion chamber. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
2. While discussing piston slap: Technician A says that it is a high-pitched clicking that becomes louder during deceleration caused by detonation. Technician B says that it is the noise made by the piston when it contacts the cylinder wall due to excessive clearances. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
3. While determining the cause for air leaking out of the oil dipstick tube during a cylinder leakage test: Technician A says that a burnt exhaust or intake valve is indicated. Technician B says that a warped cylinder head or bad head gasket is indicated. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
4. While diagnosing the cause for an engine having good results from a compression test and cylinder leakage test but poor results from a cylinder power balance test: Technician A says that incorrect valve timing is the most likely cause. Technician B says that a collapsed lifter is a likely cause. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
5. While looking at the results of an oil pressure test: Technician A says that higher than normal readings can be caused by a defective pressure regulator. Technician B says that higher than normal readings can be expected on a cold engine. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
6. A vehicle is producing a sharp, metallic rapping sound originating in the upper portion of the engine. It is most noticeable during idle. Technician A diagnoses the problem as piston pin knock. Technician B says that the problem is most likely a loose crankshaft thrust bearing. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
7. While conducting an engine vacuum test: Technician A says that a steady low vacuum reading can be caused by a burned intake valve. Technician B says that an overall low vacuum reading is caused by something that affects all of the engine's cylinders. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
8. While determining the most likely problem of an engine with poor compression test results but acceptable cylinder leakage readings: Technician A says that the problem may be incorrect valve timing. Technician B says that the problem is a leaking valve guide. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
9. When a customer refers to the engine component that opens and closes the intake and exhaust valves: Technician A believes that the customer is referring to the camshaft. Technician B thinks that the component in question is the intake manifold. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
10. Technician A says that if an engine had good results from a compression test, it will have good results from a cylinder leakage test. Technician B says that if an engine had good results from a cylinder leakage test, it will have good results from a compression test. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B

ENGINE DISASSEMBLY AND CLEANING

OBJECTIVES

- Prepare an engine for removal.
- Remove an engine from a FWD and a RWD vehicle.
- Separate the engine into its basic components.
- Name the three basic cleaning processes.

This chapter covers the removal and installation of an engine. It also covers basic disassembly and general cleaning of the components. The material is presented so that it applies not only to engine rebuilding, but also to the replacement of individual parts when a total rebuild is not necessary. Complete disassembly and assembly of the engine block and cylinder head are covered in Chapters 11 and 12.

Before removing the engine, clean it and the area around it. Also, check the service manual for the correct procedure for removing the engine from a particular vehicle. Make sure you adhere to all precautions given by the manufacturer.

REMOVING AN ENGINE

Make sure you have the tools and equipment required for the job before you begin. In addition to hand tools and some special tools, you will need an engine hoist or crane (**Figure 10-1**) and a jack.

The basic procedures for engine removal vary, depending on whether the engine is removed from the bottom of the vehicle or through the hood opening. Many FWD vehicles require removal of the engine from the bottom, whereas most RWD vehicles require the engine to come out from the hood opening. The engine exit point is something to keep in mind while you are disconnecting and removing items in preparation for engine removal.

General Procedures

When removing an engine, setting the vehicle on a frame contact hoist is recommended. When the vehicle is sitting on the floor, block the wheels so it does not move while you are working. Open the

Figure 10-1 To pull an engine out of a vehicle, the chain on the lifting crane is attached to another chain secured to the engine.

hood and put fender covers on both front fenders (**Figure 10-2**). Once the vehicle is in position, relieve the pressure in the fuel system using the procedures given by the manufacturer.

Customer Care

Make sure your hands, shoes, and clothing are clean before getting into a customer's car. Disposable seat and floor coverings should be used to help protect the interior.

Figure 10-2 Before doing anything, put covers on the fenders.

Battery Install a memory saver before you disconnect the battery to prevent the vehicle's computers and other devices from losing what they have stored in their memory. Disconnect all negative battery cables (**Figure 10-3**), tape their connectors, and place them away from the battery. If the battery will be in the way of engine removal, remove the positive cables and the battery.

Hood The vehicle's hood will get in the way during engine removal. If the hinges allow the hood to be set straight up above the engine compartment, prop it in that position with wood or a broom. Make sure the hood is secure before proceeding. In many cases, the hood should be removed and set aside in a safe place on fender covers or cardboard. Make sure not to damage the vehicle's paint while doing this. Before removing the hood, mark the location of the hinges on the hood. Then unbolt and remove the hood with the help of someone else.

Figure 10-3 After the negative battery cable is disconnected, tape the terminal end to prevent it from accidentally touching the battery.

Figure 10-4 Drain the engine's coolant and recycle it.

SHOP TALK

Often the safest place to store the hood is on the vehicle's roof.

Fluids Drain the engine's oil and remove the oil filter. Then drain the coolant from the radiator (**Figure 10-4**) and engine block, if possible. To increase the flow of the coolant out of the cooling system, remove the radiator cap. Make sure the engine is cool before opening the coolant drain and before removing the radiator cap. After collecting the old coolant, recycle it. If the transmission will be removed with the engine, drain its fluid.

Underbody Connections While you are under the vehicle to drain the fluids, disconnect the shift linkage, transmission cooling lines, all electrical connections, vacuum hoses, and clutch linkages from the transmission (**Figure 10-5**). If the clutch is

Figure 10-5 If the transmission will be removed with the engine, disconnect all linkages, lines, and electrical connectors.

hydraulically operated, unbolt the slave cylinder and set it aside, if possible. If this is not possible, disconnect and plug the line to the cylinder.

Air-Fuel System Remove the air intake ducts and air cleaner assembly. Disconnect and plug the fuel line at the fuel rail. If the engine is equipped with a return fuel line from the fuel pressure regulator, disconnect that as well (**Figure 10-6**). Make sure all fuel lines are closed off with pinch pliers or the appropriate plug or cap. Most late-model fuel lines have quick-connect fittings that are separated by squeezing the retainer tabs together and pulling the fitting off the fuel line nipple.

Disconnect all vacuum lines at the engine. Make sure these are labeled before disconnecting them. Most automobiles have a vacuum wiring diagram decal under the hood (**Figure 10-7**). The diagram and the labels (these could be masking tape with

the connecting point written on it) will make it easier to reconnect the hoses when the engine is reinstalled.

Now disconnect the throttle linkage at the throttle body and the electrical connector to the throttle position (TP) sensor.

SHOP TALK

Some technicians are using instant cameras or video recording cameras to help recall the locations of underhood items by taking pictures before work is started. This technique can be quite valuable considering how complex the underhood systems of current cars have become.

Accessories Remove all drive belts (**Figure 10-8**). Unbolt and move the power steering pump and

Figure 10-6 Disconnect and plug the fuel lines at the fuel rail and the pressure regulator.

Figure 10-7 An underhood decal showing the routing of vacuum lines for the vehicle.

Figure 10-8 Before removing the drive belts, pay attention to the routing of each belt.

air-conditioning (A/C) compressor out of the way. Do not disconnect the lines unless it is necessary. If the pressure hoses at the A/C compressor must be disconnected, do not loosen the fittings until the refrigerant has been captured by a refrigerant reclaimer/recycling machine. Once disconnected, plug the lines and connections at the compressor to prevent dirt and moisture from entering.

Remove or move the A/C compressor bracket, power steering pump, air pump, and any other components attached to the engine. Disconnect and plug all transmission and oil cooler lines.

SHOP TALK

When removing the fasteners, pay close attention to their size and type. The brackets used to secure accessories use different size fasteners. Mark and organize the fasteners so their proper location can be easily identified later. It is a good idea to store the fasteners in different containers, one for each system or section of the engine.

Electrical Connections Unplug all electrical wires between the engine and the vehicle. Use masking tape as a label to identify all wires that are disconnected (**Figure 10-9**). Some engines have a crankshaft position sensor attached above the flywheel

Figure 10-9 Before unplugging the electrical wires between the engine and the vehicle, use masking tape as a label to identify all disconnected wires.

or flexplate. This sensor must be removed before separating the engine from the bell housing. Make sure the engine ground strap is disconnected, preferably at the engine.

Cooling System Disconnect the heater inlet and outlet hoses. Then disconnect the upper and lower radiator hoses. If the radiator is fitted with a fan shroud, carefully remove it along with the cooling fan. If the vehicle is equipped with an electric cooling fan, disconnect the wiring to the cooling fan. Then unbolt and remove the radiator mounting brackets and remove the radiator. Normally the electric cooling fan assembly and radiator can be removed as a unit (**Figure 10-10**).

Figure 10-10 Typically the electric cooling fans can be removed as a unit with the radiator.

Figure 10-11 The exhaust system must be disconnected to remove the engine. Often this is the condition of the exhaust, so take care not to damage anything.

Miscellaneous Stuff Disconnect the exhaust system; attempt to do this at the exhaust manifold (**Figure 10-11**). When disconnecting the exhaust system, make sure the wires connected to the exhaust sensors are disconnected before the system is moved. Remove any heat shields that may be in the way of moving or removing the exhaust system. Now carefully check under the hood to find and remove anything that may interfere with engine removal.

Removing the engine from a RWD vehicle is more straightforward than removing one from a FWD model, because there is typically easy access to the cables, wiring, and bell housing bolts. Engines in FWD cars can be more difficult to remove because large assemblies such as engine cradles, suspension components, brake components, splash shields, or other pieces may need to be disassembled or removed.

FWD Vehicles

Before removing the engine, identify any special tool needs and precautions that are recommended by the manufacturer. Most often the engine in a FWD vehicle is removed through the bottom of the vehicle. Special tools may be required to hold the transaxle and/or engine in place as it is being disconnected from the vehicle (**Figure 10-12**). Always refer to the service manual before proceeding to remove the transaxle. You will waste much time and energy if you do not check the manual first.

When the engine is removed through the bottom of the vehicle, use an engine cradle and dolly to support the engine. If the manufacturer recommends engine removal through the hood opening, use an engine hoist. Regardless of the method of removal, the engine and transaxle are usually removed as a

Figure 10-12 A transverse engine support bar provides the necessary support when removing an engine from a FWD vehicle. *Courtesy of SPX Service Solutions*

Figure 10-13 Use a large breaker bar to loosen the axle shaft hub nuts.

unit. The transaxle can be separated from the engine once it has been lifted out of the vehicle.

Drive Axles Using a large breaker bar, loosen and remove the axle shaft hub nuts (**Figure 10-13**). It is recommended that these nuts be loosened with the vehicle on the floor and the brakes applied.

Raise the vehicle so you can comfortably work under it. Then remove the wheel and tire assemblies from the front wheels. Tap the splined CV joint shaft with a soft-faced hammer to see if it is loose. Most will come loose with a few taps. Many Ford FWD cars use an interference fit spline at the hub. You will need a special puller for this type of CV joint; the tool pushes the shaft out, and on installation pulls the shaft back into the hub.

Disconnect all suspension and steering parts that need to be removed according to the service manual.

Figure 10-14 Pull the steering knuckle outward to allow the CV joint shaft to slide out of the hub.

Index the parts so wheel alignment will be close after reassembly. Normally the lower ball joint must be separated from the steering knuckle. The ball joint will either be bolted to the lower control arm or the ball joint will be held into the knuckle with a pinch bolt. Once the ball joint is loose, the control arm can be pulled down and the knuckle can be pushed outward to allow the CV joint shaft to slide out of the hub (Figure 10-14).

The inboard joint can then either be pried out or will slide out. Some transaxles have retaining clips that must be removed before the inner joint can be removed. Others have a flange-type mounting. These must be unbolted to remove the shafts. In some cases, flange-mounted drive shafts may be left attached to the wheel and hub assembly and only unbolted at the transmission flange. The free end of the shafts should be supported and placed out of the way.

Pull the drive axles out of the transaxle. While removing the axles, make sure the brake lines and hoses are not stressed. Suspend them with wire to relieve the weight on the hoses and to keep them out of the way.

Transaxle Connections Disconnect all electrical connectors and the speedometer cable at the transaxle. Then disconnect the shift linkage or cables and the clutch cable.

Starter Now, remove the starter. The starter wiring may be left connected, or you can also completely remove the starter from the vehicle to get it totally out of the way. The starter should never be left to hang by the wires attached to it. The weight of the starter can damage the wires or, worse, break the wires and allow the starter to fall, possibly on you or someone else. Always securely support the starter and position it out of the way after you have unbolted it from the engine.

Figure 10-15 Some engines are equipped with eye plates to which the hoist can be safely attached.

Removing the Engine through the Hood Opening

Connect the engine sling or lifting chains to the engine. Use the lifting hooks on the engine (Figure 10-15) or fasten the sling to the points given in the service manual. Connect the sling to the crane and raise the crane just enough to support the engine.

From under the vehicle, remove the cross member. Then remove the mounting bolts for the engine at the engine and transmission mounts. With the transmission jack supporting the transmission, remove the transaxle mounts.

From under the hood, remove all remaining mounts. Raise the engine slightly to free it from the mounts. Then slowly raise the engine from the engine compartment. Guide the engine around all wires and hoses to make sure nothing gets damaged. Once the engine is cleared from the vehicle, prepare to separate it from the transaxle.

Removing the Engine from under the Vehicle

Position the engine cradle and dolly under the engine. Adjust the pegs of the cradle so they fit into the recesses on the bottom of the engine, and secure the engine.

Remove all engine and transmission mount bolts. If required, remove the frame member from the vehicle. It may also be necessary to disconnect the steering gear from the frame. Double-check to ensure that all wires and hoses are disconnected from the engine. With the transmission jack supporting the transmission, remove the transaxle mounts.

Slowly raise the vehicle, lifting it slightly away from the engine. As the vehicle is lifted, the engine remains on the cradle. During this process, continually check for interference with the engine and the body of the

vehicle. Also watch for any wires and hoses that may still be attached to the engine. Once the vehicle is clear of the engine, prepare to separate the engine from the transaxle.

RWD Vehicles

The engine is removed through the hood opening with an engine hoist on most RWD vehicles. Refer to the service manual to determine the proper engine lift points. Attach a pulling sling or chain to the engine. Some engines have eye plates for lifting. If they are not available, the sling must be bolted to the engine. The sling attaching bolts must be large enough to support the engine and must thread into the block a minimum of $1\frac{1}{2}$ times the bolt diameter.

If the transmission is being removed with the engine, position the hook of the engine hoist to the lifting chain so that the engine tips a little toward the transmission. Lift the engine slightly and check for any additional things behind and under the engine that should be disconnected.

Transmission If the engine and transmission must be separated before engine removal, remove all clutch (bell) housing bolts. If the vehicle has an automatic transmission, remove the torque converter mounting bolts.

If the transmission is being removed with the engine, place a drain pan under the transmission and drain the fluid from the transmission. Once the fluid is out, move the drain pan under the rear of the transmission. Use chalk to index the alignment of the rear U-joint and the pinion flange (**Figure 10-16**). Then remove the drive shaft.

Disconnect all electrical connections and the speedometer cable at the transmission. Make sure

you place these away from the transmission so they are not damaged during transmission removal or installation.

Disconnect and remove the transmission and clutch linkage. Disconnect the parts of the exhaust system that may get in the way. It is best to do this by disconnecting as little as possible.

Use a transmission jack to securely support the transmission (**Figure 10-17**) and unbolt the motor mounts. If the engine is removed with its transmission, the front of the engine must come straight up as the transmission moves away from the bottom of the vehicle. Remove the transmission mount and cross member (**Figure 10-18**).

Removing the Engine Center the boom of the crane (hoist) directly over the engine and raise the engine slightly. Make sure the engine is securely fastened to the chain and that nothing else is still attached to the engine. Continue raising the engine while pulling it forward. Make sure that the engine does not bind or damage anything in the engine compartment while doing this. When the engine is high enough to clear the front of the vehicle, roll the crane and engine away from the vehicle.

Figure 10-16 Mark the alignment of the rear U-joint and the pinion flange before removing the drive shaft.

Figure 10-17 Use a transmission jack to securely support the transmission before removing the motor mounts.

Figure 10-18 If the engine is removed with its transmission, remove the transmission mount and cross member.

Figure 10-19 Once the engine is removed and is hanging on the engine hoist, lower it close to the floor so it can be safely moved to the work area.

Lower the engine close to the floor so it can be transported to the desired location (**Figure 10-19**). If the transmission was removed with the engine, remove the bell housing bolts and inspection plate bolts. On vehicles with an automatic transmission, also remove the torque converter-to-flexplate bolts. Use a C-clamp or other brace to prevent the torque converter from falling. Also mark the location of the torque converter in relation to the flexplate.

ENGINE DISASSEMBLY AND INSPECTION

Raise the engine and position it next to an engine stand (**Figure 10-20**). Mount the engine to the engine stand with bolts. Most stands use a plate with several holes or adjustable arms. The engine must be sup-

Figure 10-20 A typical engine stand. Courtesy of SPX Service Solutions

ported by at least four bolts that fit solidly into it. The engine should be positioned so that its center is in the middle of the engine stand's adapter plate. This will ensure that the engine is not too heavy when rotated on the engine stand.

In most cases, the flywheel or flexplate must be removed to mount the engine on its stand. Mark the position of the flywheel on the crankshaft. This aids the reassembly of the engine. To do this, loosen—but do not remove—the attaching bolts in a “star” pattern to reduce the chance of distorting the flywheel. At times, the flywheel will turn with the wrench as the bolts are being loosened. When this happens, a flywheel lock should be used to stop the flywheel from turning. Once all of the bolts are loosened, take hold of the flywheel while removing the bolts. The flywheel can be quite heavy and if it falls, you can be injured or the flywheel can be damaged. The flywheel for manual transmissions should be inspected for possible damage and for signs of clutch problems. Place the flywheel on a flat surface.

Once the engine is securely mounted to the engine stand, remove the sling or lifting chain. The engine can now be disassembled and cleaned. Always refer to the service manual before you start to disassemble an engine.

Slowly disassemble the engine and visually inspect each part for any signs of damage. Look for excessive wear on the moving parts. Check all parts for signs of overheating, unusual wear, and chips. Look for signs of gasket and seal leakage.

USING SERVICE INFORMATION

Look up the specific model car and engine prior to disassembling the engine.

Cylinder Head Removal

The first step in disassembly of an engine is usually the removal of the intake and exhaust manifolds. On some inline engines, the intake and exhaust manifolds are often removed as an assembly.

SHOP TALK

It is important to let an aluminum cylinder head cool before removing it.

To start cylinder head removal, remove the valve cover or covers and disassemble the rocker arm components (**Figure 10-21**) according to the guidelines given by the manufacturer. Check the rocker area for sludge. Excessive buildup can indicate a poor maintenance schedule and is a signal to look for wear on other components.

Figure 10-21 Remove the valve cover and disassemble the rocker arm components. Check the rocker area for sludge. Keep the rocker arms or rocker arm assemblies in the order they were installed.

On OHC engines, the timing belt cover must be removed. Under the cover is the timing belt or chain and sprockets. In the service information, there will be a description of the type and location of the timing marks on the crankshaft and camshaft sprockets. If possible, rotate the crankshaft to check the alignment of the sprockets. If the shafts are not aligned, make note of this for later reference. The valves will hit the pistons on some engines when the timing belt or chain slips, skips, or breaks. These engines are commonly called **interference engines**. When the valves hit the piston, they will bend. The valves in **freewheeling engines** will not hit the piston when valve timing is off. However, the keys and keyways in the camshaft sprocket may be damaged.

Interference engines typically have a decal on the cam cover that states the belt must be changed at a particular mileage interval. Potential valve and/or piston damage is the reason why timing belt replacement is recommended.

The belt or chain must be removed before removing the cylinder head. Locate and move the belt's tensioner pulley to remove its tension on the belt. Slip the belt off the camshaft and crankshaft sprockets, if possible.

When removing the cylinder head, keep the pushrods and rocker arms or rocker arm assemblies in exact order. Use an organizing tray or label the parts with a felt-tipped marker to keep them together and labeled accurately. This type of organization greatly aids in diagnosing valve-related problems. Remove the lifters from the block and place them in the order they were installed.

The cylinder head bolts are loosened one or two turns each, following the pattern specified by the manufacturer (**Figure 10-22**). The sequence is typically the opposite of the tightening sequence. If there is no specified procedure, the bolts ought to be

Figure 10-22 When loosening cylinder head bolts; follow the sequence given by the manufacturer.

Figure 10-23 A major buildup of sludge on the bottom of this oil pan.

loosened one or two turns, beginning in the ends and working toward the center. This prevents the distortion that can occur if bolts are all loosened at once. The bolts are then removed and the cylinder head can be lifted off. The cylinder head gasket should be saved to compare with the new head gasket during reassembly. Set the cylinder head(s) on cardboard or another soft surface to prevent damage to the sealing surfaces.

Go To

Chapter 12 for the procedures for disassembling and servicing cylinder heads.

The water pump is normally mounted to the front of the engine. Unbolt and remove it. Rotate the engine block so the oil pan is up. Remove the pan's attaching bolts. Then lift off the oil pan. Once the pan is removed, look inside for metal shavings and sludge (**Figure 10-23**). Both of these are indications of problems. Disassembly of the engine block can begin now.

Go To

Chapter 11 for the procedures for disassembling and servicing engine short blocks.

CLEANING ENGINE PARTS

After the component that needs service has been disassembled, its parts should be thoroughly cleaned (**Figure 10-24**). The cleaning method depends on the

Figure 10-24 From (A) grime to (B) shine.

component and the type of equipment available. An incorrect cleaning method or agent can often be more harmful than no cleaning at all. For example, using caustic soda to clean aluminum parts will dissolve the part. **Caustic soda** is a strong detergent that is commonly found in solvents that are effective in removing carbon.

WARNING!

Always wear the appropriate eye protection and gloves when working with cleaning solvents.

Only after all components have been thoroughly and properly cleaned can an effective inspection be made or proper machining be done.

Types of Contaminants

Being able to recognize the type of dirt you are to clean will save you time and effort. Basically there are four types of dirt.

Water-Soluble Soils The easiest dirt to clean is **water-soluble** soils, which includes dirt, dust, and mud.

Organic Soils **Organic soils** contain carbon and cannot be effectively removed with plain water. There are three distinct groupings of organic soils:

- Petroleum by-products derived from crude oil, including tar, road oil, engine oil, gasoline, diesel fuel, grease, and engine oil additives

- By-products of combustion, including carbon, varnish, gum, and sludge
- Coatings, including such items as rust-proofing materials, gasket sealers and cements, paints, waxes, and sound-deadener coatings

Rust **Rust** is the result of a chemical reaction that takes place when iron and steel are exposed to oxygen and moisture. Corrosion, like rust, results from a similar chemical reaction between oxygen and metal containing aluminum. If left unchecked, both rust and corrosion can physically destroy metal parts quite rapidly. In addition to metal destruction, rust also acts to insulate and prevent proper heat transfer inside the cooling system.

Scale When water containing mineral and deposits is heated, suspended minerals and impurities tend to dissolve, settle out, and attach to the surrounding hot metal surfaces. This buildup of minerals and deposits inside the cooling system is known as **scale**. Over a period of time, scale can accumulate to the extent that passages become blocked, cooling efficiency is compromised, and metal parts start to deteriorate.

Cleaning with Chemicals

There are three basic processes for cleaning automotive engine parts. The first process that is discussed is chemical cleaning.

This method of cleaning uses chemical action to remove dirt, grease, scale, paint, and/or rust.

CAUTION!

When working with any type of cleaning solvent or chemical, be sure to wear protective gloves and goggles and work in a well-ventilated area. Prolonged immersion of the hands in a solvent can cause a burning sensation. In some cases a skin rash might develop. There is one caution to mention about all manufactured cleaning materials that cannot be overemphasized: Read the labels carefully before mixing or using.

Unfortunately, the most traditional line of defense against soils involves the use of cleaning chemicals. Chlorinated hydrocarbons and mineral spirits may have some health risks associated with their use through skin exposure and inhalation of vapors. Hydrocarbon cleaning solvents are also flammable.

The use of water-based nontoxic chemicals can eliminate such risks.

WARNING!

Prior to using any chemical, read through all of the information given on the material safety data sheet (MSDS) or the Canadian workplace hazardous materials information systems sheets (WHMIS) for that chemical. Become aware of the health hazards presented by the various chemicals.

Hydrocarbon solvents are labeled hazardous or toxic and require special handling and disposal procedures. Many water-based cleaning solutions are biodegradable. Once the cleaning solution has become contaminated with grease and grime, it too becomes a hazardous or toxic waste that can be subject to the same disposal rules as a hydrocarbon solvent.

Some manufacturers offer waste-handling and solvent recycling services. The old solvent is recycled by a distillation process to separate the sludge and contaminants. The solvent is then returned to service and the contaminants disposed of. Independent services for maintaining hot tanks and spray washers are also available.

CAUTION!

Care needs to be taken with alloy blocks with sleeves or liners. The different metals react differently to chemicals. Make sure to check with the service manual before using a cleaning solution on these parts. The wrong chemical can cause damage to the block and/or sleeves.

Chemical Cleaning Machines

Parts Washers Parts washers (often called **solvent tanks**) are one of the most widely used and inexpensive methods of removing grease, oil, and dirt from the metal surfaces of a seemingly infinite variety of automotive components and engine parts. A typical washer setup (**Figure 10-25**) might consist of a tank to hold a given volume of solvent cleaner and some method of applying the solvent. These methods include soaking, soaking and agitation, solvent streams, and spray gun applicators.

Figure 10-25 A typical parts washer.

Soak Tanks There are two types of soak tanks: cold and hot. Cold soak tanks are commonly used to clean carburetors, throttle bodies, and aluminum parts. A typical cold soak unit consists of a tank to hold the cleaner and a basket to hold the parts to be cleaned. After soaking with or without gentle agitation is complete, the parts are removed, flushed with water, and blown dry with compressed air.

Cleaning time is short, about 20 to 30 minutes, when the chemical cleaner is new. The time becomes progressively longer as the chemical ages. Agitation by raising and lowering the basket (usually done mechanically) will reduce the soak period to about 10 minutes. Some more elaborate tanks are agitated automatically.

Hot soak tanks are actually heated cold tanks. The source of heat is electricity, natural gas, or propane. The solution inside the hot tanks usually ranges from 160°F to 200°F (71°C to 93°C). Most tanks are generally large enough to hold an entire engine block and its related parts.

Hot tanks use a simple immersion process that relies on a heated chemical to lift the grease and grime off the surface. Liquid or parts agitation may also be used to speed up the job. Agitation helps shake the grime loose and also helps the liquid penetrate blind passageways and crevices in the part (**Figure 10-26**). Generally speaking, it takes one to several hours to soak most parts clean.

Hot Spray Tanks The hot spray tank (**Figure 10-27**) works like a large automatic dishwasher and removes organic and rust soils from a variety of automotive parts. As with the hot soak method, spray washers soak the parts, but they also have the benefit of moderate pressure cleaning.

Figure 10-26 A hot soak (d.p) tank.

Figure 10-27 A hot spray cleaning machine.
Courtesy of Better Engineering Mfg., Inc.

Using a hot jet spray washer can cut cleaning time to less than 10 minutes. Normally, a strong soap solution is used as the cleaning agent. The speed of this system, along with lower operating costs, makes it popular with many machine shop owners.

SHOP TALK

Caustic soda, also known as sodium hydroxide, can be a very dangerous irritant to the eyes, skin, and mucous membranes. These chemicals should be used and handled with care. Because of the accumulation of heavy metals, it is considered a hazardous waste material and must be disposed of in accordance with EPA guidelines.

Spray washers are often used to preclean engine parts prior to disassembly. A pass-through spray washer is fully automatic once the parts have been loaded, and the cabinet prevents the runoff from going down the drain or onto the ground (which is not permitted in many areas because of local waste disposal regulations). Spray washers are also useful for post-machining cleanup to remove machine oils and metal chips.

Thermal Cleaning

The second basic process for cleaning engine parts is thermal cleaning. This process relies on heat to bake off or oxidize dirt and other contaminants.

Thermal cleaning ovens (**Figure 10-28**), especially the pyrolytic type, have become increasingly popular. The main advantage of thermal cleaning is a total reduction of all oils and grease on and in blocks, heads, and other parts. The high temperature inside the oven (generally 650°F to 800°F [343°C to 426°C]) oxidizes all the grease and oil, leaving behind a dry, powdery ash on the parts. The ash must then be removed by shot blasting or washing. The parts come

Figure 10-28 A cleaning furnace. Courtesy of Pollution Control Products Co.

out dry, which makes subsequent cleanup with shot blast or glass beads easier because the shot will not stick.

SHOP TALK

A slow cooling rate is recommended to prevent distortion that could be caused by unequal cooling rates within complex castings.

One of the major attractions of cleaning ovens is that they offer a more environmentally acceptable process than chemical cleaning. But although there is no solvent or sludge to worry about with an oven, the ash residue that comes off the cleaned parts must still be handled according to local disposal regulations.

Abrasive Cleaners

The third process used to clean engine parts involves the use of abrasives. Most abrasive cleaning machines are used in conjunction with other cleaning processes rather than as a primary cleaning process itself.

Cleaning by Hand Some manual cleaning is inevitable. Heavy buildups of grease and/or carbon should initially be removed by scraping or wire brushing. Cleaning aluminum and other soft metals with either technique should be done with extreme care, especially while using a steel scraper or brush. Steel or plastic scrapers are used to remove old gasket material from a surface and heavy sludge. Power tools with a small sanding disc (normally emery cloth) are available (**Figure 10-29**). These are designed to remove all soft materials without damaging the hard metal surface. After the item has been scraped, an additional cleaning method is used to finalize cleaning.

Carbon can be removed with a handheld wire brush or a wire wheel driven by an electric or air drill motor (**Figure 10-30**). Moving the wire wheel in a

Figure 10-29 Using a power scraper pad will prevent any metal from being removed.

Figure 10-30 Carbon can be removed with a wire wheel driven by an electric or air drill motor.

light circular motion against the carbon helps to crack and dislodge the carbon. Some shops use a wire brush in addition to another cleaning method.

Wire brushes are also used to clean the inside of oil and coolant galleries. The brushes are soaked in a cleaning solvent and then passed through the passages in the block. To do this, the gallery plugs must be removed (**Figure 10-31**).

Abrasive Blaster Compressed air shot and grit blasters are best used on parts that will be machined after they have been cleaned. Two basic types of media are available: shot and grit. Shot is round; grit is angular in shape. Parts must be dry and grease-free when

Figure 10-31 It is often necessary to remove the gallery plugs and hand clean the oil galleries.

Figure 10-32 Using a blast nozzle to clean the backside of a valve.

they go into an abrasive blast machine. Otherwise, the shot or beads will stick. Steel shot and glass beads are used for cleaning and/or peening the part's surfaces. **Peening** is a process of hammering on the surface. This packs the molecules tighter to increase the part's resistance to fatigue and stress. Steel shot is normally used with airless wheel blast equipment, which hurls the shot at the part by the centrifugal force of the spinning wheel. Glass beads are blown through a nozzle by compressed air in an enclosure (**Figure 10-32**).

Grit is primarily used for aggressive cleaning or on surfaces that need to be etched to improve paint adhesion. However, it removes metal, which can lead to some changes in tolerances. Grit blasting also chews out pits in the surface into which pollutants and blast residue can settle. This leads to stress corrosion unless the surface is painted or treated. These tiny crevices can also form surface stresses in the metal, which can lead to cracking in highly loaded parts. Grit should never be used for peening. Steel and aluminum oxide are the two most common types of grit.

Parts Tumbler A cleaning alternative that can save considerable labor when cleaning small parts such as engine valves is a tumbler. Various cleaning media can be used in a tumbler to scrub the parts clean. This saves considerable hand labor and eliminates dust. In some tumblers, all parts are rotated and tilted at the same time.

Vibratory Cleaning Shakers, as they are frequently called, use a vibrating tub filled with ceramic, steel, porcelain, or aluminum abrasive to scrub parts clean (**Figure 10-33**). Most shakers flush the tub with solvent to help loosen and flush away the dirt and grime.

Figure 10-33 A vibratory parts cleaner. Courtesy of C & M TOPLINE

The solvent drains out the bottom and is filtered to remove the sludge.

Alternative Cleaning Methods

Three of the most popular alternatives to traditional chemical cleaning systems are ultrasonic cleaning, citrus chemicals, and salt baths.

Ultrasonic Cleaning This cleaning process has been used for a number of years to clean small parts like jewelry, dentures, and medical instruments. Recently, however, the use of larger ultrasonic units has expanded into small engine parts cleaning. **Ultrasonic cleaning** (Figure 10-34) utilizes high-frequency sound waves to create microscopic bubbles that burst into energy to loosen soil from parts. Because the tiny bubbles do all the work, the chemical content of the cleaning solution

Figure 10-34 An ultrasonic parts cleaner.

is minimized, making waste disposal less of a problem. At the present time, however, the initial cost and handling capacity of ultrasonic equipment is its major disadvantage.

Citrus Chemicals Some chemical producers are starting to develop citrus-based cleaning chemicals as a replacement for the more hazardous solvent and alkaline-based chemicals currently used. Because of their citrus origin, these chemicals are safer to handle, easier to dispose of, and even smell good.

Salt Bath The **salt bath** is a unique process that uses high-temperature molten salt to dissolve organic materials, including carbon, grease, oil, dirt, paint, and some gaskets. For cast iron and steel, the salt bath operates at about 700°F to 850°F (371°C to 454°C). For aluminum or combinations of aluminum and iron, a different salt solution is used at a lower temperature (about 600°F [315°C]). The contaminants precipitate out of the solution and sink to the bottom of the tank, where they must be removed periodically. The salt bath itself lasts indefinitely as long as the salt is maintained properly. Cycling times with a salt bath are fairly quick, averaging 20 to 30 minutes. Like a hot tank, the temperature of the salt bath is maintained continuously.

CRACK DETECTION

Once engine parts have been cleaned, everything should be carefully inspected. This inspection should include a check for cracks, especially in the engine block and cylinder head. If cracks in the metal casting are discovered during the inspection, they should be repaired or the part replaced.

Cracks in metal castings are the result of stress or strain in a section of the casting. This stress or strain finds a weak point in that section of the casting and causes it to distort or separate at that point (Figure 10-35). Such stresses or strains in castings can develop from the following:

- Pressure or temperature changes during the casting procedure may cause internal material structure defects, inclusion, or voids.
- Fatigue may result from fluctuating or repeated stress cycles. It might begin as small cracks and progress to larger ones under the action of the stress.
- Flexing of the metal may result due to its lack of rigidity.
- Impact damage may occur by a solid, hard object hitting a component.

Figure 10-35 Examples of stress cracks.

- Constant impacting of a valve against a hardened seat may produce vibrations that could possibly lead to fracturing a thin-walled casting.
- Chilling of a hot engine by a sudden rush of cold water or air over the surface may happen.
- Excessive overheating is possible due to improper operation of an engine system.

Methods

Cracks can be found by visual inspection; however, many are not easily seen (**Figure 10-36**). Therefore, engine rebuilders use special equipment to detect cracks, especially if there is reason to suspect a crack.

Pressure Checks Pressure checking a cylinder block or head is done in the same way a tire is checked for leaks. All of the coolant passages are plugged with

Figure 10-36 The topside oil artery crack appeared when an oxyacetylene flame was passed over the casting. Carbon in the flame was trapped in the crack, highlighting it.

Figure 10-37 MPI testing passes a magnetic field through the iron item being checked.

rubber stoppers or gaskets. Compressed air is injected into a water jacket and the point of air entry is sealed. The block or head is then submerged into water. Bubbles will form in the water if there is a leak. The spot where the bubbles are forming is the location of the leak.

Magnetic Checks Magnetic particle inspection (MPI) uses a permanent or electromagnet to create a magnetic field in a cast iron unit (**Figure 10-37**). When the legs of the detector tool are placed on the metal, the magnetic field travels through the metal. Iron filings are sprinkled in the surface to detect a secondary magnetic field resulting from a crack (**Figure 10-38**). Because the secondary magnetic field will not form if the crack is in the same direction as the magnet, the magnet must be rotated and the metal checked in both directions.

Dye Penetrant Another common way to detect cracks is by using three separate chemicals:

Figure 10-38 A crack will cause two opposing magnetic poles to form on each side; the iron filings used with the magnet will show these fields.

Figure 10-39 Cracks appear as red lines when a dye penetrant is used. Courtesy of LOCK-N-STITCH Inc.

penetrant, cleaner, and developer. The part to be checked must be clean and dry. This check must be done according to the following sequence:

1. Spray or brush the penetrant onto the surface.
2. Wait 5 minutes.
3. Spray the cleaner onto a clean cloth.
4. Wipe off all visible penetrant.
5. Spray the developer on the tested area.
6. Wait until the developer is totally dry.
7. Inspect the area. Cracks will appear as a red line (Figure 10-39).

Crack Repair

If a crack is found, a decision must be made as to whether the part should be replaced or repaired. This decision should be based on the cost of repair as well as any other repair that the part may need. Further inspection of the cylinder block and head and the service and repair procedures for each are covered in the Chapters 11 and 12.

CASE STUDY

A four-cylinder engine is brought into the shop. The customer complains of excessive oil consumption and oil leaks. Compression and cylinder leakage tests indicate that the cylinders are sealing well, and a power balance test indicates that all of the cylinders are producing about the same amount of power.

Based on these results, the technician assumes that the problem is leaking valve seals. The initial plan is to replace the seals and regasket the engine.

It is odd that the engine has both of these problems. It has less than 50,000 miles on it. Not really sure if the problems are related, the technician proceeds to disassemble the engine. Upon removing the valve cover, large amounts of sludge are evident throughout the valve train. This is normally a sign that the engine has been neglected. However, a review of the files indicates that the oil has recently been changed. In fact, the car has been well maintained. Is the sludging related to the oil consumption and leaks?

The oil pan is removed and additional sludge is found. The cylinder head is then removed from the block. The piston tops and the combustion chamber are covered with a thick black carbon coating. Is this buildup related to other problems?

The cylinder head is disassembled and each of the valve seals is found to be deteriorated. What could cause the deterioration of rubber parts, leaking gaskets, sludging, and carbon buildup in the cylinders? After careful thought, the technician pays attention to the parts taken off the engine during initial disassembly. A thorough inspection is made of the PCV system and it is discovered that the hose that connects the valve to the manifold is plugged solid. The valve is also found to be plugged.

The PCV system is designed to remove crankcase fumes and pressure from the crankcase. These fumes can cause rapid sludging of the oil and deterioration of rubber parts. Excessive crankcase pressure can cause leaks, as the pressure seeks to relieve itself. A faulty PCV valve can cause all of the problems exhibited by this engine. In fact, it is the cause of the problems.

The engine is resealed and new valve stem seals are installed. The engine is then installed with a new PCV valve and hose. Not only is the customer's complaint taken care of, but so is the cause of the problem.

KEY TERMS

Caustic soda	Salt bath
Freewheeling engines	Scale
Interference engines	Solvent tank
Organic soils	Ultrasonic cleaning
Peening	Water soluble
Rust	

SUMMARY

- When preparing an engine for removal and disassembly, it is important to always follow the specific service manual procedures for the particular vehicle being worked on.
- A hoist and chain are needed to lift an engine out of its compartment. Mount the engine to an engine stand with a minimum of four bolts, or set it securely on blocks.
- While an engine teardown of both the cylinder head and block is a relatively standard procedure, exact details vary among engine types and styles. The vehicle's service manual should be considered as the final word.
- An understanding of specific soil types can save time and effort during the engine cleaning process. The main categories of contaminants include water-soluble and organic soils, rust, and scale.
- Protective gloves and goggles should be worn when working with any type of cleaning solvent or chemical. Read the label carefully before using as well as all of the information provided on material safety data sheets.
- Parts washers, or solvent tanks, are a popular and inexpensive means of cleaning the metal surfaces of many automotive components and engine parts. Regardless of the type of solvent used, it usually requires some brushing, scraping, or agitation to increase the cleaning effectiveness.
- Cold soak tanks are used to clean carburetors, throttle bodies, and aluminum parts. Hot soak tanks, which can accommodate an entire engine block, use a heated cleaning solution to boil out dirt. Hot heat spray washers have the added benefit of moderate pressure cleaning.
- Alternatives to caustic chemical cleaning have emerged in recent years, including ultrasonic cleaning, salt baths, and citrus chemical cleaning. These methods are all growing in popularity.
- The main advantage of thermal cleaning is its total reduction of all oils and grease. The high temperatures inside the oven leave a dry, powdery ash on the parts. This is then removed by shot blasting or washing.
- Steel shot and glass beads are used for cleaning operations where etching or material removal is not desired. Grit, the other type of abrasive blaster, is used for more aggressive cleaning jobs.
- Some degree of manual cleaning is necessary in any engine rebuilding job. Very fine abrasive paper should be used to remove surface irregularities. A handheld or power wire brush is also helpful, though it can be time-consuming to work with.
- There are three common methods for detecting cracks in the metal casting of engine parts: using a magnet and magnetic powder (iron filings), using penetrant dye (especially for aluminum heads and blocks), and pressuring with air.

REVIEW QUESTIONS

1. What should be worn when working with any type of cleaning solvent or chemical?
2. *True or False?* Most engines in a RWD vehicle must be removed with the transmission still attached.
3. What is the best way to lift a vehicle when preparing to remove an engine?
 - a. frame contact hoist
 - b. drive on lift
 - c. hydraulic jack and safety stands
 - d. engine hoist
4. *True or False?* The first step in disassembling an engine is usually the removal of the intake and exhaust manifolds.
5. Which of the following statements is *not* true?
 - a. When the engine is removed through the bottom of the vehicle, use an engine cradle and dolly to support the engine.
 - b. If the manufacturer recommends engine removal through the hood opening, use an engine hoist.
 - c. Regardless of the method of removal, the engine and transaxle in a FWD vehicle are usually removed as a unit.
 - d. The transaxle can be separated from the engine after the engine is off its mounts.

6. The buildup of minerals and deposits inside the cooling system is called _____.
 - a. organic soil
 - b. scale
 - c. rust
 - d. grime
7. Hydrocarbon solvents are _____.
 - a. flammable
 - b. toxic
 - c. both a and b
 - d. neither a nor b
8. *True or False?* On many FWD vehicles, the suspension system must be partially disassembled to remove the radiator.
9. Which cleaning method uses high-frequency sound waves to create microscopic bubbles that loosen dirt from parts?
 - a. ultrasonic
 - b. salt bath
 - c. thermal
 - d. caustic
10. Parts must be _____ when they go into an abrasive blast machine.
 - a. wet
 - b. dry
 - c. grease-free
 - d. both b and c
11. An engine block should be mounted to an engine stand using a minimum of _____ bolts.
 - a. four
 - b. six
 - c. three
 - d. five
12. Which of the following is *not* considered part of the organic soil grouping?
 - a. petroleum by-products derived from crude oil, including tar, road oil, engine oil, gasoline, diesel fuel, grease, and engine oil additives
 - b. rust that is a product of coolant and aluminum
 - c. by-products of combustion, including carbon, varnish, gum, and sludge
 - d. coatings, including such items as rust-proofing materials, gasket sealers and cements, paints, waxes, and sound-deadener coatings
13. Why should a memory saver be installed before disconnecting a vehicle's battery?
14. Which of the following statements is *not* true about thermal cleaning?
 - a. The main advantage of thermal cleaning is a total reduction of all oils and grease on and in blocks, heads, and other parts.
 - b. After a part has been thermally cleaned, it should be submerged in water to cool it quickly.
 - c. Thermal cleaning leaves behind a dry, powdery ash on the parts.
 - d. After a part has been thermally cleaned, it should be washed or blasted with shot.
15. Which of the following is *not* a common way to identify the location of cracks in the engine block or cylinder head?
 - a. pressure checks
 - b. vacuum test
 - c. magnetic particle inspection
 - d. penetrant dye

ASE-STYLE REVIEW QUESTIONS

1. While working on an engine with an excessive amount of sludge buildup: Technician A says that the presence of sludge is a signal to look for wear on other components. Technician B says that excessive buildup can indicate a poor maintenance schedule. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
2. While discussing the common causes for cracks developing in a cylinder block or head: Technician A says that the chilling of a hot engine by a sudden rush of cold water or air over the surface may cause cracking. Technician B says that excessive overheating is a common cause. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
3. Technician A uses a crane to remove an engine from its compartment. Technician B uses an engine cradle to remove an engine from its compartment. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
4. While removing a cylinder head: Technician A keeps all rocker arms and pushrods in order. Technician B loosens each head bolt, starting with the center bolts and moving toward the ends. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B

5. While discussing abrasive cleaners: Technician A says that shot is angular in shape and is used for aggressive cleaning. Technician B says that grit is an angular-shaped media and is used to peen metal surfaces. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
6. Technician A labels or marks all electrical wires before disconnecting them. Technician B labels or marks all vacuum hoses and verifies the connections to the underhood decal before disconnecting them. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
7. While discussing cleaning engine parts: Technician A says that the cleaning method used depends on the component to be cleaned and the type of cleaning equipment available. Technician B says that sometimes it is best to clean parts by hand with soap and warm water. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
8. While loosening the axle shaft hub nuts on a FWD vehicle: Technician A says that a large breaker bar should be used to prevent damage to the bearings. Technician B says that these nuts should be loosened with the vehicle on the floor and the brakes applied. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
9. While preparing to remove an engine: Technician A disconnects the refrigerant lines at the air-conditioning compressor and allows the refrigerant to totally leak out before removing the compressor. Technician B installs plugs in the ends of the refrigerant hoses after they have been disconnected. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
10. After removing the vehicle's hood in preparation for removing the engine: Technician A places the hood on the roof of the vehicle. Technician B sets the hood aside in a safe place on fender covers or cardboard. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B

LOWER END THEORY AND SERVICE

OBJECTIVES

- Describe how to disassemble and inspect an engine.
- List the parts that make up a short block and briefly describe their operation.
- Describe the major service and rebuilding procedures performed on cylinder blocks.
- Describe the purpose, operation, and location of the camshaft.
- Describe the four types of camshaft drives.
- Inspect the camshaft and timing components.
- Describe how to install a camshaft and its bearings.
- Explain crankshaft construction, inspection, and rebuilding procedures.
- Explain the function of engine bearings, flywheels, and harmonic balancers.
- Explain the common service and assembly techniques used in connecting rod and piston servicing.
- Explain the purpose and design of the different types of piston rings.
- Describe the procedure for installing pistons in their cylinder bores.
- Inspect, service, and install an oil pump.

The lower end of an engine is the cylinder block assembly. This includes the block, camshaft, crankshaft, bearings, pistons, piston rings, and oil pump. Many of these parts are made by casting or forging. To **cast** is to form molten metal into a particular shape by pouring it into a mold. To **forge** is to form metal into a shape by heating it and pressing into a mold. Some forging is done with cold metals. These manufactured parts then undergo a number of machining operations. Following are a few examples:

- The top of the block must be perfectly smooth so that the cylinder head can seal it.
- The bottom of the block is also machined to allow for proper sealing of the oil pan.
- The cylinder bores must be smooth and have the correct diameter to accept the pistons.
- The main bearing area of the block must be aligned (cut a series of holes in a straight line) to a diameter that will accept the crankshaft. Camshaft bearing bores must also be aligned.

When there is a major engine failure, shops either rebuild or replace the engine (**Figure 11-1**). Most often the **short block** is repaired or replaced as an assembly. A basic short block consists of a cylinder

Figure 11-1 A cutaway showing the fit of the piston assemblies and crankshaft in an engine block.

block, crankshaft, bearings, connecting rods, pistons and rings, and oil gallery and core plugs. Parts related to the short block but not necessarily included with it are the flywheel and harmonic balancer. A short block may also include the engine's camshaft and timing gear. A **long block** is basically a short block with cylinder heads. These terms are commonly used when purchasing replacement engines.

SHORT BLOCK DISASSEMBLY

This chapter begins with the assumption that the engine has been removed and the cylinder head(s) have been separated from the cylinder (engine) block. However, few parts have been removed from the short block. If the oil pan and water pump are still attached to the block, remove them before proceeding.

Remove the **harmonic balancer**, also called a vibration damper. The harmonic balancer is an assembly of an inner hub bonded with rubber to an outer ring. Its purpose is to absorb the torsional vibrations of the crankshaft. Removal of the balancer requires the correct type puller (**Figure 11-2**). If a jawed puller is used, it is very likely that the rubber bonding will be damaged. This would make the balancer useless and can cause engine vibrations and crankshaft damage. Once the balancer is removed, carefully check the rubber for tears or other damage. If there are any faults, replace the balancer.

On overhead valve engines, remove the timing cover. Under the cover are the timing gears. The timing sprocket on the crankshaft snout has a slight interference fit and can normally be pulled off by hand. However, the camshaft sprocket and chain must be removed with the crankshaft sprocket. The camshaft sprocket is either press-fit or bolted to the camshaft.

Before removing the gears and chain, check the deflection of the timing chain. Depress the chain at its midway point between the gears and measure the amount that the chain can be deflected. If the deflection measurement exceeds specifications, the timing chain and gears should be replaced.

Loosen the camshaft sprocket and pull the timing gears and chain from the engine. Be careful not to

lose the keys in each shaft or any shims that may be behind the sprockets.

Often the timing chain assembly has tensioners and guides. The timing gear assembly is normally replaced during an engine overhaul. The tensioners and guides wear and should be replaced as well.

The timing belt or chain on OHC engines has already been loosened before the cylinder head was removed. However, it may still be dangling around the crankshaft sprocket. Slip it off, if possible. Unbolt the timing chain or belt cover and gently pry it away from the engine block and cylinder head. Remove the crankshaft position sensor, timing chain guide, chain tensioner slipper, and chain. Pull the timing gear or sprocket off the crankshaft. On some engines, the oil pump is driven by the crankshaft at the front of the engine. The pump should be unbolted and removed. Rotate the crankshaft counterclockwise to align the timing marks on the oil pump sprocket with the mark on the oil pump. Remove the attachment bolt for the sprocket and the chain tensioner plate and spring. Then remove the oil pump sprockets and chain. Remove the oil screen then the oil pump (**Figure 11-3**). On some engines, the alignment of the inner and outer gears of the pump should be marked before removing the pump.

If the lifters have not been removed, do so now. Place them on a bench in the order they were removed. Carefully pull the camshaft out of the block. Support the camshaft during removal to avoid dragging its lobes over the surfaces of the camshaft bearings. This can damage the bearings and lobes. Some engines require the removal of a thrust plate before removing the camshaft.

Figure 11-2 The harmonic balancer should be removed with the correct puller.

Figure 11-3 On some engines, the oil pump is driven by the crankshaft at the front of the engine.

Cylinder Block Disassembly

Rotate the engine on its stand so that the bottom is facing up. Remove the oil pan if it was not removed previously. Then remove the oil pump as directed in the service manual. Be careful not to lose the drive shaft while pulling the pump off the engine.

If the engine has balance shafts, check the thrust clearance of the shafts before removing the assembly. Set a dial indicator so it can read the back-and-forth movement (end play) of the shaft. Measure the total distance that the shaft is able to move in the housing. Compare that reading to specifications. If the reading is more than the specified maximum, the balance shaft housing and bearings should be replaced. Unbolt the housing following the sequence given in the shop manual (**Figure 11-4**).

Remove the housing cover. Then lift the balance shaft(s) out of the housing. Inspect the bearings for unusual wear or damage. Keep the bearings in their original location or mark them for identification. Check the journals of the balance shafts for scratches, pitting, and other damage. If a bearing or journal is damaged, replace the bearings and/or balance shaft.

Rotate the engine so the bottom is at the bottom again. Rotate the crankshaft so that the piston of one cylinder is at BDC. Carefully remove the cylinder ridge with a ridge reamer tool. Rotate the tool clockwise with a wrench to remove the ridge (**Figure 11-5**). Do not cut too deeply, because an indentation may be left in the bore. Remove just enough metal to allow the piston assembly to slip out of the bore without causing damage to the bore.

The ridge is formed at the top of the cylinder. Because the top ring stops traveling before it reaches

Figure 11-4 The balance shaft housing must be unbolted in the prescribed order to prevent shaft and housing warpage.

Figure 11-5 A ridge reamer should be used on all cylinders before removing the pistons.

Figure 11-6 Normal cylinder wear. Courtesy of Dana Corporation

the top of the cylinder, a ridge of unworn metal is left (**Figure 11-6**). Carbon also builds up above this ridge, adding to the problem. If the ridge is not removed, the piston's ring lands may be damaged as the piston is driven out of its bore.

Repeat the process on all cylinders. After removing the ridges, use an oily rag to wipe the metal cuttings out of the cylinder. The cuttings will stick to it.

Rotate the engine to put the bottom side up. Check all connecting rods and main bearing caps for correct position and numbering. If the numbers

Figure 11-7 Check all connecting rods and main bearing caps for correct position and numbering. If the numbers are not visible, use a center punch or number stamp to number them.

are not visible, use a center punch or number stamp to number them (**Figure 11-7**). Caps and rods should be stamped on the external flat surface. If the rods are already numbered or marked, make sure the marks designate the cylinder where the rods should be installed. They may have been installed incorrectly or they may have been taken from another engine. Re-mark them to show their current location.

To remove the piston and rod assemblies, position the crankshaft throw at the bottom of its stroke. Remove the connecting rod nuts and cap. Remember that the caps and rods must remain as a set. Tap the cap lightly with a soft hammer or wood block to aid in cap removal. Cover the rod bolts with protectors to avoid damage to the crankshaft journals. Carefully push the piston and rod assembly out with the wooden hammer handle or wooden drift and support the piston by hand as it comes out of the cylinder. Be sure that the connecting rod does not damage the cylinder wall during removal. With the bearing inserts in the rod and cap, replace the cap (numbers on the same side) and install the nuts. Repeat the procedure for all piston and rod assemblies.

In the specified order, loosen and remove the main bearing cap bolts and main bearing cap. Keeping the main bearing caps in order is very important. The location and position of each main bearing cap should be marked. Most high-performance engines have a main bearing girdle or bearing support. These use at least four bolts at each main bearing. It is important that the recommended bolt loosening sequence be followed.

After removing the main bearing caps, carefully take out the crankshaft by lifting both ends equally to avoid bending and damage. Store the crankshaft in a vertical position to avoid damage.

Remove the rear main oil seal and main bearings from the block and caps. Examine the bearing inserts

Figure 11-8 The bearings on the left have no babbit left, and the ones on the right are slightly worn and scored.

Figure 11-9 Inspect each crankshaft journal for damage and wear. *Courtesy of Dana Corporation*

for signs of abnormal engine conditions such as embedded metal particles, lack of lubrication, anti-freeze contamination, oil dilution, and uneven wear (**Figure 11-8**). Also inspect them for any unusual signs of wear, and check them for indications that they are over- or undersized. Then carefully inspect the main journals on the crankshaft for damage (**Figure 11-9**).

Engine blocks have **core plugs**, also called expansion plugs. Sand cores are used when a block is made. These cores are partly broken and dissolved when the hot metal is poured into the mold. To get the sand out, the block is made with holes. These core holes are machined and core plugs are installed to seal them (**Figure 11-10**). Blocks are also made with passageways for oil. These are machined in after the block is made and are sealed with plugs.

The block cannot be thoroughly cleaned unless all core plugs and oil plugs are removed. To remove cup-type “freeze”/core plugs, drive them in on a slant and use channel lock pliers to pull them out. Flat-type plugs can be removed by drilling a hole near the center and inserting a slide hammer to pull it out. On some engines, the cup-type plug can be easily removed by driving the plug out from the backside with a long rod.

Figure 11-10 Core plugs in an engine block.

Sometimes removing threaded front and rear oil gallery plugs can be difficult. Using a drill and screw extractor can help.

SHOP TALK

Using heat to melt paraffin into the threads of oil plugs will make removal much easier. As the part is heated, it will expand and the paraffin will leak down between the threads. Because the paraffin serves as a lubricant, you will be able to loosen the plug. Hot paraffin burns, so wear gloves when handling it.

After cleaning, the block and its parts must be visually checked for cracks or other damage.

CYLINDER BLOCK

The cylinder block houses the areas where combustion takes place. It is normally a one-piece casting that is machined so that all the parts contained in it fit properly. Blocks may be cast from different materials such as iron, aluminum (**Figure 11-11**), magnesium, or possibly, in the future, plastic. A few engine blocks have an exterior made of magnesium and the interior (cylinders, coolant passages, etc.) of a cast-iron insert. Some late-model blocks are made of two pieces: an upper unit that contains the cylinders and a lower one that surrounds the crankshaft (**Figure 11-12**). Other blocks have main cap girdles (also referred to as the bedplate) integrated in the housing to provide added strength.

Cast-iron blocks are very strong but heavy. Many engines have an aluminum block to reduce the vehicle's overall weight. Certain materials are added to aluminum to make it stronger and less likely to warp from the heat of combustion. The cylinder walls of

Figure 11-11 An engine block for a 12-cylinder engine. Courtesy of BMW of North America, LLC

Figure 11-12 Aluminum engine blocks are often two-piece units. Courtesy of Toyota Motor Sales, U.S.A., Inc.

aluminum blocks may be treated with a special coating or may have a sleeve or liner to serve as cylinder walls.

Cylinder Liners

Most aluminum blocks have cylinder liners (**Figure 11-13**). The liners are normally made of a cast-iron alloy. On some engines, the liners can be replaced

Figure 11-13 A cylinder block and cylinder liner for a late-model aluminum V8 engine. *Courtesy of Chrysler LLC*

and/or machined if they are damaged. Most are very thin and cannot be serviced and the block must be replaced if the walls are damaged. Liners are pressed into the block or are placed in the mold before the block is cast. The liners have ribs on their outside diameter. These ribs hold the liner in place and increase its ability to dissipate heat to the block. There are two types of sleeves: wet and dry. The dry sleeve is supported from top to bottom by the block. The wet sleeve is supported only at the top and bottom. Coolant touches the center part of a wet sleeve.

Lubrication and Cooling

A cylinder block contains a series of oil passages that allow engine oil to be pumped through the block and crankshaft and on to the cylinder head. Water jackets are also cast in the block around the cylinder bores. Coolant circulates through these jackets to transfer heat away.

Some engine blocks are cast with a plastic spacer for the water jackets (**Figure 11-14**). The spacers provide a uniform distribution of heat throughout the cylinders by directing the flow of coolant toward the normally hotter areas. For example, a spacer is used to direct coolant away from the center of the cylinder

Figure 11-14 If the engine has water jacket spacers, they must be removed before cleaning the block and to prevent damage to them.

bore to the top and bottom of the bore. The top and bottom of the bore are normally the hotter areas, so suppressing the coolant flow to the center may result in the center having the same temperature as the top and bottom.

Other Features

An engine block has other features. Many of these are machined areas on which to mount other parts. These areas typically include threaded bores. Brackets and housings may also be cast onto the basic block. Some blocks have air passage holes near the bottom to allow for any pressure buildup caused by the pumping action of the pistons. The bottoms of the pistons are moving with pumping action at the same time the tops are moving through their strokes.

CYLINDER BLOCK RECONDITIONING

Before doing any service to the block, clean all threaded bores with the correct-size thread chaser to remove any burrs or dirt. Use a bottoming tap in any blind holes. These bores should be slightly **chamfered** to eliminate thread pulls and jagged edges. If there is damage to the threads, they should be repaired. To restore damaged threads in an aluminum part, a threaded insert should be installed in the bore.

Check the block for cracks and other damage. Cast-iron blocks can be checked by magnafluxing. Aluminum blocks are checked for cracks with penetrant dye and a black light. Some cracks can be repaired; however, if they are in critical areas, the block should be replaced.

Deck Flatness

The top of the block where the cylinder head mounts is called the **deck**. To check deck warpage, use a precision straightedge and feeler gauge. With the straightedge positioned diagonally across the deck, the amount of warpage is determined by the size of feeler gauge that fits into the gap between the deck and the straightedge (**Figure 11-15**).

Some engines have special deck flatness requirements. Always refer to the manufacturer's specifications. If the deck is warped beyond limits, the block should be decked or replaced. Decking requires a special grinder that will shave off small amounts of metal, leaving a flat surface. Some manufacturers do not recommend decking, especially if the block is aluminum. If the block has more than one deck surface (such as a V-type engine), each deck should be machined to the same height. If the deck is warped

Figure 11-15 Checking for deck warpage with a straightedge and feeler gauge.

and not corrected, the valve seats can distort when the head is tightened to the block. Coolant and combustion leakage can also occur.

Cylinder Bore Inspection

Inspect the cylinder walls for scoring, roughness, or other signs of wear. Dirt can accelerate ring and cylinder wall wear. It also can get caught in the piston rings and can grind away at the metal surfaces.

Scuffed or scored pistons, rings, and cylinder walls (**Figure 11-16**) can act as passages for oil to bypass the rings and enter the combustion chamber. Scuffing and scoring occur when the oil film on the cylinder wall is ruptured, allowing metal-to-metal contact of the piston rings on the cylinder wall. Cooling system hot spots, oil contamination, and fuel wash are typical causes of this problem.

Most cylinder wear occurs at the top of the ring travel. Pressure on the top ring is at a peak and lubrication at a minimum when the piston is at the top of its stroke. A ridge of unworn material will remain above the upper limit of ring travel. Below the ring

Figure 11-16 A scored cylinder wall.

Figure 11-17 To check for taper, measure the diameter of the cylinder at A and C. The difference between the two readings is the amount of taper.

travel area, wear is negligible because only the piston skirt contacts the cylinder wall.

A properly reconditioned cylinder must have the correct diameter, have no taper or out-of-roundness, and the surface finish must be such that the piston rings will seat to form a seal that will control oil and minimize blowby.

Taper is the difference in diameter between the bottom of the cylinder bore and the top of the bore just below the ridge (**Figure 11-17**). Subtracting the smaller diameter from the larger one gives the cylinder taper. Some taper is permissible, but normally not more than 0.006 inch (0.1524 mm). If the taper is less than that, reboring the cylinder is not necessary.

Cylinder out-of-roundness is the difference of the cylinder's diameter when measured parallel with the crank and then perpendicular to the crank (**Figure 11-18**). Out-of-roundness is measured at the top of the cylinder just below the ridge. Typically the maximum allowable out-of-roundness is 0.0015 inch (0.0381 mm). Normally a cylinder bore is checked for out-of-roundness with a dial bore gauge (**Figure 11-19**). However, a telescoping gauge can also be used.

When using a dial bore gauge or a telescoping gauge, make sure the measuring arms are parallel to the plane of the crankshaft. The best way to do this is to rock the gauge until the smallest reading is obtained.

Cylinder Bore Surface Finish

The surface finish on a cylinder wall should act as an oil reservoir to lubricate the piston rings and prevent piston and ring scuffing. Having the correct cylinder wall finish is important. Piston ring faces can be

Figure 11-18 To check cylinder out-of-roundness, measure the bore in different locations. *Courtesy of Ford Motor Company*

Figure 11-19 Cylinder bore is checked for out-of-roundness with a dial bore gauge.

damaged and wear prematurely if the wall is too rough. A surface that is too smooth will not hold enough oil and scuffing may occur.

The desired finish has many small crisscross grooves (**Figure 11-20**). Ideally, these grooves cross at 50- to 60-degree angles, although anything from 20 to 60 degrees is acceptable. This finish leaves millions of tiny diamond-shaped areas to serve as oil reservoirs (**Figure 11-21**). It also provides flat areas or plateaus on which an oil film can form to separate the rings from the wall. If the angle of the crosshatch is too steep, the oil film will be too thin, causing ring and cylinder scuffing. If the angle is too flat, the pistons may hydroplane and excessive oil consumption will result.

Cylinder Deglazing If the inspection and measurements of the cylinder wall show that surface conditions, taper, and out-of-roundness are within

Figure 11-20 Ideal crosshatch pattern for cylinder walls. Courtesy of Chrysler LLC

Figure 11-21 The desired cylinder wall finish for most types of piston rings.

acceptable limits, the cylinder walls may only need to be deglazed. Combustion heat, engine oil, and piston movement combine to form a thin residue, **glaze**, in the cylinders. Glazed walls allow the piston rings to slide over them and prevent a positive seal between the walls and the rings.

It is easy to confuse glaze with the polished surface that appears in the cylinders after the engine has some miles on it. Often, glazing can be removed by wiping the cylinders with denatured alcohol or lacquer thinner. Fine honing stones can also remove glaze and leave the walls with a desired finish. Often,

Figure 11-22 Using a resilient-based, hone-type brush, commonly called a ball hone.

technicians use a ball hone to deglaze (**Figure 11-22**) and create the desired pattern on the walls of the cylinder. On many newer engines, deglazing with a ball hone or stones is not recommended. Always check the manufacturer's recommendations before deglazing or honing the cylinder walls.

Cylinder Honing A cylinder **hone** usually has three or four stones. The hone is spun by an electric motor and is moved up and down the cylinder's bore. Springs push the stones against the walls. As they rotate, a small amount of metal is removed from the walls. Honing oil flows over the stones and onto the cylinder wall to control the temperature and to flush out any metallic and abrasive residue. To achieve the correct wall finish, the correct type of stones should be used. Stones are classified by grit size: The lower the grit number, the coarser the stone. The type of piston ring that will be installed normally dictates the desirable grit.

Cylinder honing machines are available in manual and automatic models (**Figure 11-23**). Automatic models allow the technician to dial in the desired crosshatch angle. When honing a cylinder by hand, use a slow-speed (200–450 rpm) electric drill. Mount the honing tool into the drill and insert it into the bore. Adjust the stones so they fit snugly to the narrowest section of the cylinder. Move the drill and the hone up and down in the bore with short strokes.

Figure 11-23 Automatic cylinder hone machine.

Never remain in one spot too long. Squirt some honing oil on the walls and occasionally stop honing and clean the stones. Continue until the desired results are achieved.

Cylinder Boring When cylinder surfaces are badly worn or excessively scored or tapered, a **boring bar** or boring machine is used to cut the cylinders for over-size pistons or sleeves. A boring bar leaves a pattern on the cylinder wall similar to uneven screw threads. These can cause poor oil control and excessive blowby. Therefore, always hone a cylinder after it has been bored.

CAUTION!

Always wear eye protection when operating deglazing, honing, or boring equipment.

When engines are bored, oversized pistons and rings are used. These are available as 0.020" (0.50 mm), 0.030" (0.77 mm), 0.040" (1.0 mm), and 0.060" (1.5 mm) oversized.

Torque plates simulate the weight and structure of a cylinder head. They are used by engine rebuilding

shops and are fastened to the cylinder block to equalize or prevent twist and distortion when honing or boring a cylinder (**Figure 11-24**).

After servicing the walls, use plenty of hot, soapy water; a stiff-bristle brush; and a soft, lint-free cloth to clean the walls. Then rinse the block with water and allow it to thoroughly dry. Put a light coat of clean engine oil on the walls to prevent rust.

Lifter Bores

Carefully check each valve lifter bore for cracks and evidence of excessive wear. Oblong or egg-shaped bores indicate wear. If the bores are rusted, glazed, or have burrs and high spots, they can be honed with a brake wheel cylinder hone. Be careful not to remove more than 0.0005 inch of metal while honing. If the bores exceed allowable wear limits or are damaged, the engine block should be replaced.

Checking Crankshaft Saddle Alignment

If the block is warped and its main bearing bores are out of alignment (**Figure 11-25**), the crankshaft will bend as it rotates. This causes bearing failure and possibly a broken crankshaft. Blocks that are not severely

Figure 11-25 An exaggerated view of crankcase housing misalignment.

Figure 11-26 A line boring machine for correct crankshaft saddle alignment.

warped can be repaired by **line boring** them. This is a special machining operation in which the main bearing bores are cut to an oversize in order to keep perfect alignment (**Figure 11-26**). Badly warped blocks are replaced.

The alignment of the crankshaft saddle bore can be checked with a precisely ground arbor placed into the bearing bores. The arbor is rotated in the bores; the effort required to rotate it indicates the alignment of the bores.

Saddle alignment can also be checked with a metal straightedge (**Figure 11-27**). Place the straightedge in the saddles. Attempt to slide a feeler gauge that is half the maximum specified oil clearance under the straightedge. If this can be done at any saddle, the saddles are out of alignment and the block must be line-bored.

The roundness of the bearing saddles should be checked with a dial bore gauge or telescoping gauge and micrometer. To do this, install and tighten the main bearing caps, then measure the inside diameter in many places in each bore.

Figure 11-27 Checking bore alignment with a straightedge and feeler gauge. Courtesy of Federal-Mogul Corp.

Installing Core Plugs

After the block has been serviced and cleaned, new oil and core plugs should be installed. The plugs' bores should be inspected for any damage that would interfere with the proper sealing. Make sure the plugs are the correct size and type. Coat the plug or bore lightly with a nonhardening oil-resistant (oil gallery) or water-resistant (cooling jacket) sealer. The oil plugs are threaded into their bores. If the threads are damaged, run a tap through the bore.

If the bore for a core plug is damaged, it should be bored out for an oversized plug. Oversize (OS) plugs are identified by the OS stamped on the plug. The correct way to install a core plug depends on the type of plug.

Disc- or Dished-Type These fit in a bore with the dished side facing out (**Figure 11-28A**). With a hammer, hit the center of the disc's crown and drive the plug in until just the crown becomes flat. This allows the plug to expand properly and have a tight fit.

Cup-Type These are installed with the flanged edge outward (**Figure 11-28B**). The bore for these plugs has its largest diameter at the outer (sealing) edge. The outside of the cup must be positioned behind the chamfered edge of the bore to effectively seal the bore.

Expansion-Type These are installed with the flanged edge inward (**Figure 11-28C**). The bore for these plugs has its largest diameter at the back of the bore. The base of the plug must be positioned at the rear of the bore to seal it.

CAMSHAFTS

A camshaft (**Figure 11-29**) has a cam for each exhaust and intake valve. Each cam has a lobe that controls the opening of the valves. The height of the lobe is proportional to the amount the valve will open. The camshaft in older engines had an eccentric to operate the fuel pump and a gear to drive the distributor and oil pump. Some diesel engines have cam lobes for fuel injectors, fuel injection pumps, and/or air starting valves. The camshaft fits in a bore above the crankshaft. The bore is either in the center of the block or slightly off to one side, unless the engine has overhead camshafts. Many camshafts are cast iron or steel; others are forged steel units. To reduce weight and add strength, the camshaft in many late-model engines is a steel tube with lobes welded to it.

On OHV engines, the camshaft lobes work with lifters, pushrods, and rocker arms to open the valves.

Figure 11-28 Core plug installation methods: (A) dished, (B) cup, and (C) expansion.

Figure 11-29 A camshaft for a V8 engine. Courtesy of Melling Automotive Products

As the cam lobe rotates, it pushes up on the lifter, which moves the pushrod and one end of the rocker arm up. Since a rocker arm is a lever, as that end goes up, the other moves down. This action pushes down on the valve to open it. As the cam continues to rotate, the valve spring closes the valve while maintaining contact between the valve and the rocker arm, thereby keeping the pushrod and the lifter in contact with the rotating cam.

OHC engines may have separate camshafts for the intake and exhaust valves. As these camshafts rotate, the lobes directly open the valves or open them indirectly with cam followers, rocker arms, or bucket-type tappets. The closing of the valves is still the responsibility of the valve springs. Service to the camshaft(s) in an OHC engine is usually part of the procedures for reconditioning the engine's cylinder head.

A camshaft is driven by the crankshaft at half its speed. This is accomplished through the use of a camshaft drive gear or drive sprocket that is twice as large as the crankshaft sprocket. During one full rotation of the camshaft, the intake and exhaust valves open and close once. To synchronize the opening and closing of the valves with the position and movement of the pistons, the camshaft is timed to the crankshaft.

In the valve timing diagram (Figure 11-30) valve action is shown in relation to crankshaft rotation. The

Figure 11-30 Typical valve timing diagram.

intake valve starts to open at 21 degrees BTDC and remains open until it has traveled 51 degrees past BDC. The number of degrees between the valve's opening and closing is called intake valve duration time (252 degrees). The exhaust stroke begins at 57 degrees before BDC and continues until 15 degrees ATDC. The total exhaust valve duration is 252 degrees. The specifications for the camshaft used for the figure show the duration of the intake valve to be the same as the exhaust. This is typical; however, some camshafts are designed with different durations for the intake and exhaust valves. These camshafts are called dual-pattern cams. Different engine designs require different valve opening and closing times. Therefore, each engine design has a unique camshaft.

The actual design of the cams and lobes varies with the type of lifter or follower used in the engine. There are four distinct types of lifters: solid nonroller, hydraulic nonroller, solid roller, and hydraulic roller. Camshafts designed for solid and hydraulic nonroller cams are often called "flat-tappet" cams. A camshaft must be matched with the type of lifter for which it was designed.

Camshaft Terminology

Many different terms are used to define the specifications of a camshaft. The actual shape of a cam lobe is called the cam profile. The profile determines the duration and lift provided by the camshaft. Valve overlap is controlled by the placement of the lobes on the camshaft.

Camshaft **duration** is how long the cam holds the valves open. It is expressed in crankshaft degrees. The width of the lobe determines the cam's duration. Lift is the distance the lobe moves the lifter or follower to open the valve. Maximum lift is determined by the height of the lobe. The valve is fully open only when the lifter is at the top of the lobe. Camshaft lift does not always express how far the valve is open. Rocker arms increase the actual amount of valve opening.

Both valves are open slightly at the end of the exhaust stroke and the beginning of the intake stroke; this is called valve **overlap**. Overlap is critical to exhaust gas scavenging. A camshaft with a long overlap helps empty the cylinders at high engine speeds for improved efficiency. However, since both valves are open for a longer period, low-rpm cylinder pressure tends to drop. Because the amount of overlap has an effect on cylinder pressure, it affects overall engine efficiency and exhaust emissions. Valve overlap also helps get the intake mixture moving into the cylinder. As the exhaust gases move out of the cylinder, a low pressure is present in the cylinder. This low pressure causes atmospheric pressure to push the

intake charge into the cylinder. Less overlap provides for more pressure in the cylinder at low speeds, resulting in more torque at lower speeds.

Performance TIP Installing a camshaft with a different profile is a popular way to increase the performance of an engine. Choosing the right cam for an engine can be tricky. There are many things that must be considered, such as performance goals, type of transmissions, the weight of the vehicle, and other modifications made to the engine. Most camshaft suppliers offer guidelines for choosing the right cam. Basically, opening the valves more and keeping them open longer allows more air and fuel into the engine but allows more mixture to escape through the exhaust. Longer duration camshafts improve high engine speed performance but weaken low-speed power. Lower duration improves low-speed torque, but it limits high-speed power. Typically if the vehicle is driven mostly on the street, a camshaft with a modest increase in duration and higher lift is best.

Lobe Terminology Other terms are used to describe a camshaft's profile:

- **Base Circle**—The base circle is the cam without its lobe. It is also the part of the cam where valve adjustments are made.
- **Nose**—The nose is the highest portion of the cam lobe measured from the base circle. This point provides for the maximum amount of lift.
- **Ramp (Flank)**—The ramps are the sides of a cam lobe that lie between the nose and base circle. The ramp on one side is for valve opening and the other for valve closing. How quickly a valve will open and close depends on the steepness of the ramp.
- **Clearance Ramps**—Clearance ramps are at the very beginning or end of the opening and closing ramps. The opening clearance ramp removes any slack in the valve train before applying pressure against the valve spring to open the valve. The closing clearance ramp restores that clearance. These clearance ramps are important to the durability of the valve train.
- **Lobe Separation**—Lobe separation is the angle formed by the centerlines of the intake and exhaust lobes. This angle is measured at the camshaft and the degree rating reflects the angle at the camshaft and has nothing to do with crankshaft rotation. If the maximum lift points of the

intake and exhaust lobes are 105 degrees apart, the camshaft has a 105-degree lobe separation angle. Lobe separation angle has a direct relationship to amount of overlap. The larger or wider the separation, the less overlap there is.

Timing Mechanisms

The camshaft and crankshaft must always remain in the same relative position to each other. They must also be aligned to each other. The alignment is initially set by matching marks on the gears for both shafts; these are called timing marks. The following are the basic configurations for driving the camshaft.

Belt Drive Sprockets on the crankshaft and the camshaft are linked by a continuous neoprene belt. The belt has square-shaped internal teeth that mesh with teeth on the sprockets. The timing belt is reinforced with nylon or fiberglass to give it strength and prevent stretching. This drive configuration is limited to OHC engines. Most technicians replace the belt any time it has been removed.

Chain Drive Sprockets on the camshaft and the crankshaft are linked by a continuous chain. The sprocket on the crankshaft is steel. The sprocket on the camshaft is steel on heavy-duty applications. When quiet operation is a goal, an aluminum sprocket with nylon teeth is used. Nearly all OHV engines use a chain drive system. Chain drives are also used on many OHC engines, especially DOHCs. Often multiple chains are used and arranged in an elaborate fashion. Most chain drives have a chain tensioner to maintain proper tightness and different silencing pads to reduce chain noise.

Gear Drive A gear on the crankshaft meshes directly with a gear on the camshaft. The crankshaft gear is usually iron or steel. The camshaft gear is steel on heavy-duty applications, or aluminum or pressed fiber when quiet operation is a major consideration. The gears are helical. Helical gears are strong and tend to push the camshaft backward to help prevent it from walking out of the block.

Tensioners There is a tensioner on long chain and belt drives. The tensioner may be spring loaded and/or hydraulically operated. Its purpose is to keep the belt or chain under the correct tension as it wears and stretches. All belts and chains have a drive or tension side and a slack side. The tension side is the side that is always being pulled. The tensioner is positioned on the slack side and presses in on the belt or chain.

Variable Valve Timing Previously, variable intake and exhaust timing was only possible with overhead cams. DaimlerChrysler became the first manufacturer to produce a cam-in-block engine with independent control of exhaust camshaft timing. This system was introduced in the 2008 Dodge Viper SRT10's 8.4-liter engine. This is the first production pushrod equipped engine with true **variable valve timing (VVT)**. The VVT system electronically adjusts valve overlap by changing exhaust valve opening times in response to engine speed and load. The system provides an increase in horsepower and torque. It also reduces fuel consumption and exhaust emissions.

This VVT system uses a special camshaft and phaser. The phaser is attached to the end of the camshaft. Inside the phaser are vanes that move within a fixed cavity inside a sealed hub. The movement of the vanes is controlled by oil pressure. The applied oil pressure is controlled by the powertrain control module (PCM). The PCM transmits a signal to a solenoid to move a valve spool that regulates the flow of oil to the phaser cavity. As the applied oil pressure increases, the vanes move against spring pressure. Each vane can rotate a total of 22.5 degrees inside its chamber.

The camshaft is actually two camshafts: an inner shaft and an outer hollow tube-type shaft. It is a camshaft within a camshaft. The exhaust lobes are attached to the outer shaft and the intakes are pinned to the inner camshaft through slots in the outer tube (**Figure 11-31**). Locking pins pass through the slots and are driven through the intake cam lobe assemblies. The exhaust lobes are pressed into position on the hollow outer shaft.

The phaser hub is fit with an external gear that is driven, via a chain, by the crankshaft. The vanes are connected to the outer tube and the hub. As the vanes

Figure 11-31 The basic construction of the camshaft within a camshaft used for variable valve timing on an OHV engine.

rotate, the position of the exhaust lobes, in relationship to the intake lobes, changes. The amount the exhaust lobes can move is limited by the size of the oil cavity and the slots in the outer tube.

Although it is possible to control both the intake and exhaust valves with this VVT system, Chrysler chose to alter only the exhaust valve timing. Its goal was to increase horsepower without causing rough idle and high emissions. By controlling exhaust valve timing, Chrysler was able to use high-performance camshaft profiles without affecting low-speed operation.

Camless Engines In the very near future, four-stroke cycle engines will not have a camshaft. In a camless engine, the valves are opened and closed electronically or with electrohydraulic devices. The electrohydraulic system uses an electromagnetic field to control hydraulic solenoids. Camless technology will allow total control of the valves' lift, duration, and overlap. This would make engines much more efficient, and there would be less engine power loss due to friction. A conventional engine loses much power through the camshaft and its drive gears and chains or belts. It is said that this technology will improve fuel economy about 20% and provide nearly 20% more low-speed torque.

Valve Lifters

Valve lifters, sometimes called **cam followers** or **tappets**, follow the contour or shape of the cam lobe. Lifters are either mechanical (solid) or hydraulic. Solid valve lifters provide a rigid connection between the camshaft and the valves. Hydraulic valve lifters provide the same connection but use oil to absorb the shock that results from the movement of the valve train.

Hydraulic lifters are designed to automatically compensate for the effects of engine temperature. Changes in temperature cause valve train components to expand and contract. Hydraulic lifters automatically maintain a direct connection between valve train parts.

Solid lifters do not have this built-in feature and require a clearance between the parts of the valve train. This clearance allows for component expansion as the engine gets hot. Periodic adjustment of this clearance must be made. Excessive clearance might cause a clicking noise. This clicking noise is also an indication of the hammering of valve train parts against one another, which results in reduced camshaft and lifter life.

Nonroller lifters rotate in their bore. The contact area between the cam lobe and lifter is one of the

Figure 11-32 The camshaft's lobe is tapered to cause the lifters to rotate.

highest stressed areas in an engine. Lifter rotation places this stress at different areas at the bottom of the lifter and prevents excessive wear. Cam lobes are ground with a slight taper (**Figure 11-32**), approximately 0.001 inch (0.254 mm). The diameter of the front of the lobe's base circle is different from the diameter at the rear of the lobe. The speed at which the lifter rotates in its bore depends on the amount of taper. The interface of the lifter and lobe taper also prevents the camshaft from moving to the front or rear while the engine is running.

Roller Lifters In an effort to reduce the friction of the lifter rubbing against the cam lobes—and the resulting power loss—manufacturers often use roller-type lifters. Roller lifters (**Figure 11-33**) have a roller on the camshaft end of the lifter. The roller acts as a wheel and allows the lifter to follow the contour of the cam lobe with little friction. The lifter rolls along the surface of the lobe rather than rub against it. Roller lifters may be solid or hydraulic. The hydraulic part of a

Figure 11-33 A typical roller lifter.

Figure 11-34 Roller lifters are able to follow very aggressive cam lobe designs that provide more lift at a given duration than a flat tappet.

roller lifter works in the same way as a flat hydraulic tappet.

The rollers also allow the lifter to follow aggressive cam lobe designs that provide more lift at a given duration than a flat tappet (**Figure 11-34**). The lobes on a roller camshaft have steeper ramps and a blunt nose. If the same lobe was used with flat tappets, the edge of the lifter would contact the lobe. This would cause serious damage to the lifter and cam lobe (**Figure 11-35**). Another advantage of roller lifters is that as long as they are not damaged, they can be reused on a different roller camshaft.

Roller lifters do not and should not rotate in their bores. Therefore, the lobes on roller camshafts are not tapered. To prevent the lifters from rotating, a pair of lifters may be connected by a bar. The bar prevents

Figure 11-35 The lobes on a roller camshaft can hold the valves open longer at higher lifts. If the same lobe was used with flat tappets, the edge of the lifter would contact the lobe.

the lifters from rotating but allows each lifter to move up and down independently. Some manufacturers do not use a tie-bar; rather, they use special fixtures mounted on the block to prevent lifter rotation.

Since the lobes of the camshaft are not tapered, a roller cam will tend to walk toward the front or rear of the engine block. Cam walk can cause a number of problems to the lifters and camshaft. To prevent this problem, thrust washers or cam buttons are fitted at the ends of the camshaft. These keep the camshaft in the correct position under the lifters.

Operation of Hydraulic Valve Lifters A hydraulic lifter has a plunger, oil metering valve, pushrod seat, check valve spring, and a plunger return spring housed in a hardened iron body.

When the lifter is resting on the cam's basic circle, the valve is closed and the lifter maintains a zero clearance in the valve train. Oil is fed to the lifter through feed holes in its bore. Oil pressure forces the lifter's check valve closed to keep the oil inside the lifter. This forms a rigid connection between the lifter and pushrod. When there is some clearance in the valve train, a spring between the plunger and lifter body pushes the plunger up to eliminate the clearance. As the cam lobe turns and opens a valve, the lifter's oil feed hole moves away from the oil feed in the lifter bore. New oil cannot enter the lifter. The effort to open the valve pushes the lifter's plunger down slightly. This allows a small amount of oil to leak out; this is called **leakdown**. When the lifter returns to the base of the cam, oil can again fill the lifter (**Figure 11-36**).

If a hydraulic lifter is not able to leak down or does not fill with oil, a noise will be heard from the engine.

Camshaft Bearings

The camshaft is supported by several bearings, or bushings. OHV camshaft bearings are one-piece plain bearings pressed into the camshaft bore (**Figure 11-37**). The bearings are either aluminum or steel with a lining of babbitt. **Babbitt** is a soft slippery material made of mostly lead and tin. Alloys of aluminum are commonly found in late-model engines. Aluminum bearings have a longer service life because they are harder than babbitt, but they are more susceptible to damage from dirt and poor lubrication.

OHC camshafts may be supported by split plain bearings. These split bearings are similar to main and connecting rod bearings. Camshaft bearings are normally replaced during engine rebuilding. The old bearings should be inspected for signs of unusual wear that may indicate an oiling or bore alignment problem.

Figure 11-36 Hydraulic lifter operation.

SHOP TALK

Many OHC engines do not use camshaft bearings. Rather the cylinder head is machined to provide support for the camshaft and to serve as bearing surfaces. When these surfaces are damaged, the entire cylinder head is typically replaced.

Balance Shafts

Many late-model engines have one or more balance (silence) shafts to smoothen engine operation. An engine's crankshaft is one of the main sources of engine vibration because it is inherently out of balance. Balance shafts are designed to cancel out these vibrations.

Figure 11-37 The typical camshaft bearing is a full round design.

A balance shaft has counterweights designed to mirror the throws of the crankshaft. These weights are positioned to the opposite side of the weight of the crankshaft and are rotated in the opposite direction as the crankshaft. As the engine turns, the opposing weights mutually cancel out any vibrations. Balance shafts rotate at twice the speed of the crankshaft and are synchronized or timed to the rotation of the crankshaft. If the balance shaft(s) are not timed to the crankshaft, the engine may vibrate more than it would without a balance shaft.

Balance shafts are located in the engine block on one side of the crankshaft, in the camshaft bore, or in a separate assembly bolted to the engine block (**Figure 11-38**).

Figure 11-38 Balance shaft assemblies for a four-cylinder engine. Courtesy of Toyota Motor Sales, U.S.A., Inc.

Balance shafts are inspected and serviced as part of reconditioning or building a short block. The shafts' journals and bearings need to be checked for wear, damage, and proper oil clearances. Check the bolts for the housing. If they are damaged, replace them. Use a vernier caliper to measure the length of the bolts from their seat to the end. Compare the length to specifications. If the bolts are too long, replace them. The drive chain for the shaft(s) should also be checked for stretching. This is done by pulling on two ends of the chain and measuring that length. If the length is greater than specifications, the chain should be replaced.

CRANKSHAFT

Crankshafts (**Figure 11-39**) are made of cast iron, forged cast steel, or nodular iron, and then machined. At the centerline of the crankshaft are the main bearing journals. These journals are machined to a very close tolerance because the weight and movement of the crankshaft are supported at these points. The number of main bearings varies with engine design. V-type engines have fewer main bearings than an inline engine with the same number of cylinders. A V-type engine uses a shorter crankshaft.

Offset from the crankshaft's centerline are connecting rod journals. The degree of offset and number of journals depends on engine design (**Figure 11-40**). An inline six-cylinder engine has six connecting rod journals. A V6 engine may have only three. Each journal has two rods attached to it, one from each side of the V. A connecting rod journal is also called a crank pin.

The position of the rod journals places the weight and pressure from the pistons away from the center of crankshaft. This creates an imbalanced condition. To overcome this imbalance, counterweights are added to the crankshaft. These are positioned opposite the connecting rod journals.

The main and rod bearing journals must have a very smooth surface. A clearance between the journal

Figure 11-39 A crankshaft.

Figure 11-40 Various crankshaft configurations.

and bearing is needed to allow a film of oil to form. The crankshaft rotates on this film. If the crankshaft journals become out of round, tapered, or scored, the oil film will not form properly and the journal will contact the bearing surface. This causes early bearing or crankshaft failure. The main and rod bearings are generally made of lead-coated copper or tin, or aluminum. These materials are softer than the crankshaft. This means that wear will appear first on the bearings.

It is important that the journals receive an ample supply of clean oil. Each main bearing journal has a hole drilled into it with a connecting bore or bores leading to one or more rod bearing journals. Pressurized oil moves in, over, and out of the journals.

A crankshaft has two distinct ends. One is called the flywheel end and, as its name implies, this is where the flywheel is attached. The front end or belt drive

end of the crankshaft has a snout for mounting the crankshaft timing gear and damper.

Crankshaft Torsional Dampers

Combustion causes an extreme amount of pressure in a cylinder (more than 2 tons each time a cylinder fires). This pressure is applied to the pistons and moves through the connecting rods to the crankshaft. This downward force causes the crankshaft to rotate. In an engine with more than one cylinder, this pressure is exerted at different places on the crankshaft and at different times. As a result, the crankshaft tends to twist and deflect, causing torsional harmonic vibrations. These vibrations constantly change but there are specific engine speeds where these harmonics are amplified. This increase in torsional vibration can cause damage to the crankshaft, the engine, and/or any accessories that are driven by the crankshaft.

These harmful vibrations are often limited by a torsional damper located at the front of the crankshaft. There are two common types of torsional dampers: harmonic balancers and fluid dampers. Both use friction to reduce crankshaft vibrations.

Harmonic Balancer A harmonic balancer (**Figure 11-41**), also called a vibration damper, is the most common. A harmonic balancer has a cast-iron hub and an outer cast-iron inertia ring that is connected to the hub with an elastomer (rubber) sleeve. The hub of the harmonic balancer is pressed onto the snout of the crankshaft. The inertia ring is heavy and is machined to serve as a counterweight for the crankshaft. As the crankshaft twists, the hub applies a force to the rubber. The rubber then applies this force to the inertia ring. The counterweight is snapped in the direction of crankshaft rotation to counterbalance

Figure 11-41 A vibration damper or harmonic balancer.

the torsional vibrations from the pulsating crankshaft. The connecting rod journals also snap as they receive the high pressure from combustion and the snaps cause the counterweight to snap.

To allow the outer ring to move independently of the hub, the rubber sleeve deflects slightly. The condition of this sleeve is critical to the effectiveness of the balancer. Check the condition of the rubber; look for any broken areas or tears. If it looks good, press on the rubber; it should spring back. If the balancer fails the checks, it should be replaced.

Fluid Damper This type of torsional damper is seldom used by the OEM. However, it is commonly installed by the aftermarket. They are effective in a wide range of engine speeds, especially high speeds. Fluid-filled dampers have a hub surrounded by an inertia ring. Rather than connecting the two with rubber, the outer ring encases the hub. A high-viscosity silicone fluid surrounds the hub. As the outer ring snaps in response to the snapping of the connecting rods and crankshaft, the outer ring rubs against the hub. This rubbing creates friction. The friction is absorbed by the fluid and turned into heat. Therefore, the vibrations are changed to heat and the heat is dissipated from the damper.

Flywheel

The **flywheel** also helps the engine run smoother by applying a constant moving force to carry the crankshaft from one firing stroke to the next. Once the flywheel starts to rotate, its weight tends to keep it rotating. The flywheel's inertia keeps the crankshaft rotating smoothly in spite of the pulses of power from the pistons.

Because of its large diameter, the flywheel also makes a convenient point to connect the starter to the engine. The large diameter supplies good gear reduction for the starter, making it easy for it to turn the engine against its compression. The surface of a flywheel may be used as part of the clutch. On a vehicle with an automatic transmission, a lighter **flexplate** is used. The torque converter provides the weight required to attain flywheel functions.

Flywheel Inspection Check the runout of the flywheel and carefully inspect its surface. Replacement or resurfacing may be required. Excessive runout can cause vibrations, poor clutch action, and clutch slippage. With both manual shift and automatic transmissions, inspect the flywheel for a damaged or worn ring gear. Many ring gears can be removed and flipped over if they are damaged on one side.

CRANKSHAFT INSPECTION AND REBUILDING

Check the crankshaft for the following:

- Are the vibration damper and flywheel mounting surfaces eroded or fretted?
- Are there indications of damage from previous engine failures?
- Do any of the journal diameters show signs of heat checking or discoloration from high-operating temperatures?
- Are any of the sealing surfaces deeply worn, sharply ridged, or scored?
- Are there any signs of surface cracks or hardness distress?

If any or all of these conditions are present, the parts need to be repaired or replaced.

To measure the diameter of the journals, use an outside micrometer (**Figure 11-42**). Measure them for size, out-of-roundness, and taper (**Figure 11-43**). Taper is measured from one side of the journals to the other. The maximum taper is 0.001 inch.

Compare these measurements to specifications to determine if the crankshaft needs to be reground or replaced. If the journals are within specifications, the journal area needs only to be cleaned.

USING SERVICE INFORMATION

Crankshaft specifications can be found in the engine specification section of a service manual.

Crankshaft Reconditioning

If the crankshaft is severely damaged, it should be replaced. A crankshaft with journal taper or grooves,

Figure 11-42 Measure the diameters of the crank journals with an outside micrometer.

A vs. B = Vertical taper
C vs. D = Horizontal taper
A vs. C = Out of round
B vs. D = Out of round

Check for out-of-roundness at each end of journal

Figure 11-43 Checking crankshaft journals for out-of-roundness and taper.

burnt marks, or small nicks in the journal surfaces may be reusable after the journals are refinished. This process grinds away some of the metal on the journals to provide an even and mar-free surface.

Minor journal damage may be corrected by polishing the journals with a very fine sandpaper. A polishing tool rotates a long loop of sandpaper against the journals as the crankshaft is rotated by a stand. The constant movement of the sandpaper and the rotation of the crankshaft prevent the creation of flat spots on the journals.

Checking Crankshaft Straightness

To check the straightness of the crankshaft, ensure that it is supported on V-blocks positioned on the end main bearing journals. Position a dial indicator at the 3 o'clock position on the center main bearing journal.

Set the indicator at 0 (zero) and turn the crankshaft through one complete rotation. The total deflection of the indicator, the amount greater than zero plus the amount less than zero, is the **total indicator reading (TIR)**. Bow is 50% of the TIR. Compare the bow of the crankshaft to the acceptable alignment/bow specifications.

A special machine is used to straighten crankshafts but will only be found in serious engine rebuilding shops. In most cases if the crankshaft is warped, it is replaced.

Crankshaft Bearings

Bearings are used to carry the loads created by crankshaft movement. They are a major wear item and require close inspection. Main bearings support the crankshaft journals. Connecting rod bearings connect the crankshaft to the connecting rods.

Figure 11-44 Full-round and split insert bearings.

Modern crankshaft bearings are known as insert bearings. There are two basic designs (**Figure 11-44**). A **full-round** (one-piece) **bearing** is used in bores that allow the shaft's journals to be inserted into the bearing, such as a camshaft. A **split** (two halves) **bearing** is used where the bearing must be assembled around the journal. Crankshaft bearings are the split type.

Many crankshafts have a main bearing with flanged sides. This is called a thrust bearing and is used to control the horizontal movement or end play of the shaft. Most thrust main bearings are double flanged (**Figure 11-45**). Some crankshafts use flat insert thrust bearings.

Some late-model engines do not have separate main bearing caps; rather, they are fitted with a lower engine block assembly. This assembly works like a bridge and contains the lower half of the main bearing bores. The assembly is torqued to the block.

On some engines, the main bearing caps and lower block assemblies are given additional strength

Figure 11-45 A thrust bearing with grooves cut into its flange to provide for better lubrication.

Figure 11-46 Six bolts secure each main cap in this engine. Each bolt must be tightened in correct sequence and to the correct torque.

through the use of additional bolts. The main caps are secured by four bolts, two on each side of the cap. Other designs may have additional side bolts to fasten the side of the cap to the engine block. Regardless of the number and position of the bolts, proper tightening sequences (**Figure 11-46**) must be followed.

Bearing Materials

Bearings can be made of aluminum, aluminum alloys, copper and lead alloys, and steel backings coated with babbitt. Each has advantages in terms of resistance to corrosion, rate of wear, and fatigue strength. Aluminum alloy bearings are the most commonly used. These bearings contain silicon, which helps to reduce wear. Some bearings use a combination of metals, such as a layer of copper-lead alloy on a steel backing, followed by a thin coating of babbitt (**Figure 11-47**). This design takes advantage of the excellent properties of each metal.

Bearing Spread

Most main and connecting rod bearings have “spread.” This means the distance across the outside parting edges of the bearing insert is slightly greater than the diameter of the housing bore. To position a bearing half with spread, it must be snapped into place (**Figure 11-48**). This provides a good fit inside the bore and helps keep the bearings in place during assembly.

Bearing Crush

Each half of a split bearing is made slightly larger than an exact half. This can be seen quite easily when a half is snapped into place. The parting faces extend a little beyond the seat (**Figure 11-49**). This extension is called crush. When the two halves are assembled and

Figure 11-47 The basic construction of a bearing composed of three metals. *Courtesy of Dana Corporation*

Figure 11-48 Spread requires a bearing to be lightly snapped into place.

Figure 11-49 Crush ensures good contact between the bearing and the housing.

the cap tightened, the crush forces the bearing halves into the bore. Bearing crush increases the contact area between the bearing and bore, allowing for better heat transfer, and compensates for slight bore distortions.

Bearing Locating Devices

Engine bearings must not be able to rotate or shift sideways in their bores. Many different methods are used to keep the bearings in place. The most common way is the use of a locating lug. As shown in **Figure 11-50**, this is a protrusion at the parting

Figure 11-50 The locating lug fits into the slot in the housing.

face of the bearing. The lug fits into a slot in the bearing's bore.

Oil Grooves

To ensure an adequate oil supply to the bearing's surface, an oil groove is added to the bearing. Most OEM bearings have a full groove around the entire circumference of the bearing, and others have a groove only in the upper bearing half.

Oil Holes

Oil holes in the bearings allow oil to flow through the block and into the bearing's oil clearance. These holes control the amount of oil sent to the connecting rod bearings and other parts of the engine. For example, oil squirt holes in connecting rods are used to spray oil onto the cylinder walls. The oil hole normally lines up with the groove in a bearing. When installing bearings, make sure the oil holes in the block line up with holes in the bearings.

Bearing Failure and Inspection

As shown in **Figure 11-51**, bearings can fail for many reasons. Dirt and oil starvation are the major reasons for bearing failure. Other engine problems, such as bent or twisted crankshafts or connecting rods or out-of-shape journals, can also cause bearings to wear irregularly.

INSTALLING MAIN BEARINGS AND CRANKSHAFT

Before assembling the short block, make sure the engine is thoroughly cleaned. Hot water and detergent are used to clean blocks, crankshafts, and camshafts. After the parts are cleaned, blow them dry and immediately coat them with oil to prevent rusting. Also make sure all oil passages are free of dirt and foreign particles.

A gap or clearance between the outside diameter of the crankshaft journals and the inside diameter of its bearings is necessary. This clearance allows for the building and maintenance of an oil film. Proper lubrication and cooling of the bearing depend on correct crankshaft oil clearances. Scored

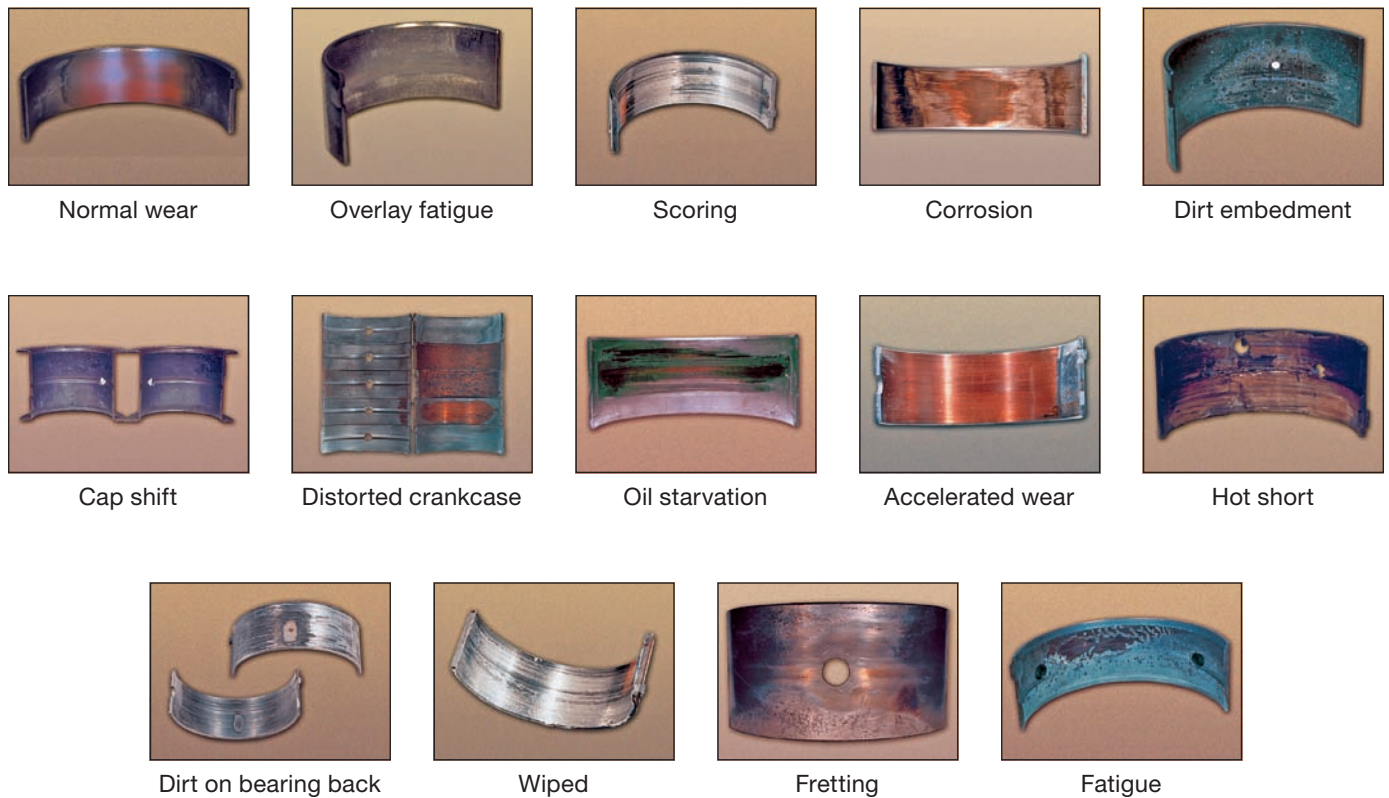

Figure 11-51 Common forms of bearing distress. *Courtesy of Dana Corporation*

bearings, worn crankshaft, excessive cylinder wear, stuck piston rings, and worn pistons can result from too small an oil clearance. If the oil clearance is too great, the crankshaft might pound up and down, overheat, and weld itself to the insert bearings.

During an engine rebuild, if there is little or no wear on the journals, the proper oil clearance can be restored with the installation of standard-size bearings. However, if the crankshaft is worn to the point where standard-size bearings will leave an excessive oil clearance, a bearing with a thicker wall must be used. Although these bearings are thicker, they are known as undersize because the journals and crankpins are smaller in diameter. In other words, they are under the standard size.

Undersize bearings are available in 0.001 inch (0.0254 mm) or 0.002 inch (0.0508 mm) sizes for shafts that are uniformly worn by that amount. Undersize bearings are also available in thicker sizes, such as 0.010 inch (0.2540 mm), 0.020 inch (0.5080 mm), and 0.030 inch (0.7620 mm), for crankshafts that have been refinished (or reground) to a standard undersize. The difference in bearing thickness is normally stamped onto the backside of the bearing. Bearings may also be color-coded to indicate their size. Often engines are manufactured with other than standard journal sizes. The crankshaft is marked to show the size of bearing used (**Figure 11-52**).

Figure 11-52 Size markings on a crankshaft, connecting rod, and rod bearing. *Courtesy of Toyota Motor Sales, U.S.A., Inc.*

If the housing bores have been machined larger by align boring or align honing, oversized bearings are used to take up this space.

Make sure the new bearings match the crankshaft journal diameters and main bearing bores. Before the bearings are installed, make sure the bore is clean and dry. Use a clean, lint-free cloth to wipe the bearing back and bore surface.

SHOP TALK

The critical bolts in most engines must be tightened with a torque-angle gauge after a specific torque has been reached. Make sure to do this. Also check the length and condition of all bolts before reusing them.

Put the new main bearings into each main bearing cap and the bearing bores in the cylinder block. Make sure all holes are aligned. The backs of the bearing inserts should never be oiled or greased. Place the crankshaft onto the bearings. The oil clearance is now measured with Plastigage. Make sure the journals are clean and free of oil. The presence of oil will give inaccurate clearance measurements.

Plastigage is fine, plastic string that flattens out as the caps are tightened on the crankshaft. The procedure for using Plastigage is shown in Photo Sequence 7.

One side of the Plastigage's package is used for inch measurements, the other for metric measurements. The string can be purchased to measure different clearance ranges. Usually, the smallest clearance range is required for engine work.

If the oil clearance is not within specifications, the crankshaft needs to be machined or replaced, or undersized bearings should be installed.

SHOP TALK

If the journals measure within specifications but they are pitted or gouged, polish the worst journal to determine whether or not grinding is necessary. If polishing achieves smoothness, then grinding is probably not necessary.

Crankshaft End Play

Crankshaft end play can be measured with a feeler gauge by prying the crankshaft rearward and measuring the clearance between the thrust bearing flange and a machined surface on the crankshaft. Insert the feeler gauge at several locations around the rear thrust

Figure 11-53 Crankshaft end play can be checked with a feeler gauge. Courtesy of Federal-Mogul Corp.

bearing face (**Figure 11-53**). You may also position a dial indicator so that the fore and aft movement of the crankshaft can be measured.

If the end play is less than or greater than the specified limits, the main bearing with the thrust surface must be exchanged for one with a thicker or thinner thrust surface. If the engine has thrust washers or shims, thicker or thinner washers or shims must be used.

Most engines require the installation of main bearing seals during the final installation of the crankshaft.

Connecting Rod

The connecting rod is used to transmit the pressure applied on the piston to the crankshaft (**Figure 11-54**). Connecting rods are able to swivel at the piston and the crankshaft. This allows them to freely move the pistons up and down while they rotate around the crankshaft. A connecting rod faces great stress. The force applied during the power stroke is applied to the connecting rod as it moves through a variety of angles. The rod has great force applied to it from the top and has great resistance to movement at the bottom. The center section of a rod is basically an "I-beam." This provides maximum strength with minimum weight.

Connecting rods are kept as light as possible. They are generally forged from high-strength steel or made of nodular steel or cast iron. Cast iron is rarely used in automotive engines. Aluminum and titanium connecting rods are also used. Aluminium rods are light and have the ability to absorb high-pressure shocks, but they are not as durable as steel rods. Titanium rods are very strong and light but are rather expensive. Some late-model engines, such as the Ford 4.6-liter and the Chrysler 2.0-liter engines, have powdered (sintered) metal connecting rods.

Checking Main Bearing Clearance with Plastigage

P7-1 Checking main bearing clearance begins with mounting the engine block upside down on an engine stand.

P7-2 Install main bearings into bores, being careful to properly seat them. Wipe the bearings with a clean lint-free rag.

P7-3 Wipe the crankshaft journals with a clean rag.

P7-4 Carefully install the crankshaft into the bearings. Try to keep the crankshaft from moving on the bearing surfaces.

P7-5 Place a piece of Plastigage on the journal. The piece should fit between the radius of the journal.

P7-6 Install the main caps in their proper locations and directions. Wipe the threads of the cap bolts with a clean rag.

P7-7 Install the cap bolts and tighten them according to the manufacturer's recommendations.

Checking Main Bearing Clearance with Plastigage (continued)

P7-8 Remove the main caps and observe the spread of the Plastigage. If the gage did not spread, try again with a larger gage.

P7-9 Compare the spread of the gage with the scale given on the Plastigage container. Compare the clearance with the specifications.

P7-10 Carefully scrape the Plastigage off the journal surface.

P7-11 Wipe the journal clean with a rag.

P7-12 If the clearance was within the specifications, remove the crankshaft and apply a good coat of fresh engine oil to the bearings.

P7-13 Reinstall the crankshaft and apply a coat of oil to the journal surfaces.

P7-14 Reinstall the main caps and tighten according to specifications.

Figure 11-54 A piston and connecting rod assembly. Courtesy of BMW of North America, LLC

These rods are light and strong and are easily identified by their smoothness.

The small end or piston pin end is made to accept the **piston pin**, which connects the piston to the rod. The piston pin can be pressed-fit in the piston and free fit in the rod. When this is the case, the small end of the rod will be fitted with a bushing. The pin can also be a free fit in the piston and pressed-fit in the rod. In this case no bushings are used. The pin simply moves in the piston using the piston hole as a bearing surface.

The “big” end of the rod is used to attach it to the crankshaft. This end is made in two pieces. The upper half is part of the rod. The lower half is called the rod cap and is bolted to the rod. The connecting rod and its cap are manufactured as a unit and must always be kept together. During production, the rod caps are either machined off the rod or are scribed and broken off. Since the cap of a powdered metal rod is broken away from the rod during manufacturing, there is an uneven mating surface due to the break and the grain of the powdered metal. When the cap is assembled on the rod, these imperfections ensure that the cap is positioned exactly where it was before it was broken off. With other rods, there is the possibility that the rod and cap will be slightly misaligned when they are assembled.

The big end is fitted with bearing inserts made of the same material as the main bearings. Many connecting rods have a hole drilled through the big end to the bearing area. The bearing insert may have a hole that is aligned with the hole in the rod’s bore. This hole supplies oil for lubricating. Some rods have an oil squirt hole. This hole sprays oil onto the cylinder wall to lubricate and cool the piston skirt. When the rod is properly installed, this squirt hole is pointed to the major thrust area of the cylinder wall.

Inspection Closely examine all piston skirts and bearings for unusual wear patterns that may indicate a twisted rod (**Figure 11-55**). Rods suspected of being bent or distorted can be checked with a rod alignment checker. Normally a damaged rod is replaced, although equipment is available to straighten them and to rebores the small and big ends. Many manufacturers recommend a check of the rod bolts before reusing them. The typical procedure involves measuring the diameter of the bolt at its tension portion.

Major misalignment

A sign of a bent and twisted rod

Figure 11-55 The effects of rod misalignment on its bearings. Courtesy of AE Clevite Engine Parts

If the diameter is less than the minimum, it should be replaced.

PISTON AND PISTON RINGS

The piston forms the lower portion of the combustion chamber. The pressures from combustion are exerted against the top of the piston, called the **head** or **dome**. A piston must be strong enough to face this pressure; however, it should also be as light as possible. This is why most pistons are made of aluminum or aluminum alloys.

Aluminum pistons alloyed with copper, magnesium, nickel, and silicon are common. Silicon is the most common element mixed with aluminum to make pistons. Silicon makes the piston more resistive to corrosion and improves its strength, hardness, and wear resistance. It also helps to reduce the piston's weight.

There are three basic types of aluminum silicon alloys used in pistons: hypoeutectic, eutectic, and hypereutectic. Hypoeutectic pistons, common in earlier engines, have about 9% silicon. Most eutectic pistons have 11% to 12% silicon. Eutectic alloys provide good strength and are economical to make. **Hypereutectic** pistons have a silicon content above 12%. They offer low thermal expansion rates, improved groove wear, good resistance to high temperatures, and greater strength and scuff and seizure resistance.

The head of the piston can be flat, concave, convex, crowned, raised and relieved for valves, or notched for valves. Newer pistons are typically flat, flat with valve notches, or have a slightly dished crown. The dished crown concentrates the pressure of com-

bustion at the thickest part of the piston head, right above the top of the piston pin boss. The piston pin boss is a built-up area around the bore for the piston pin, sometimes called the **wrist pin** (Figure 11-56). The pin bore is not always centered in the piston. It can be offset toward the major thrust side of the piston, which is the side that will contact the cylinder wall during the power stroke.

Piston heads are often coated with hard anodizing, ceramics, or electroplating. These coatings increase the hardness and resistance to corrosion, cracking, wear, and scratching. New ceramic coatings offer nearly three times the surface hardness of traditional hard-anodized coatings. Ceramic coatings also help protect against spontaneous detonation.

Just below the dome, around the sides of the piston, is a series of grooves. The grooves are used to hold the piston rings. The high parts between the grooves are called **ring lands**. Some pistons have a ceramic coating in the top ring groove to prevent the ring from being "welded" inside the groove. Normally there are three grooves: two compression and one oil control. The compression grooves are located toward the top of the piston. The depth of grooves varies with the size of the piston and the type of rings used. The oil control groove is the lowest groove on the piston. They are normally wider than the compression ring grooves and have holes or slots to allow oil to drain. The positions of the ring grooves vary with engine design. Many newer engines have the top compression ring as close as possible to the piston head. This reduces the amount of fuel that can drop down the sides of the piston before combustion. This hidden fuel is not involved in the combustion process but leaves as unburned hydrocarbons during the exhaust

Figure 11-56 The features and terminology used to describe a piston. *Courtesy of MAHLE International GmbH*

stroke. In this design, all rings are placed close together. On a few pistons, the piston pin bore is very close to the piston head, behind the groove for the lower oil control ring.

The area below the piston pin is called the **piston skirt**. The area from just below the bottom ring groove to the tip of the skirt is the piston thrust surface. There are two basic types of piston skirts: the slipper and full skirt. The full skirt is used primarily in truck and commercial engines. The slipper type is used in automobile engines and allows the piston enough thrust surface for normal operation. A slipper skirt also allows the piston to be lighter and reduces piston expansion because there is less material to hold heat.

Late-model engines that are capable of running to fairly high rpm use lighter pistons. These pistons have skirts only on the thrust sides. Often the skirts are coated with molybdenum to prevent cylinder wall scuffing.

To ensure that the piston is installed correctly and has the correct offset, the top of the piston will have a mark. The most common mark is a notch that is machined into the top edge of the piston. Always check with the service manual for the correct direction and position of the mark. The front of the piston must match the front of the connecting rod (**Figure 11-57**).

When an engine is designed, piston expansion determines how much piston clearance is required in the cylinder bore. Too little clearance will cause the piston to bind at operating temperatures. Too much will cause piston slap. The normal piston clearance for an engine is about 0.001 to 0.002 inch (0.0254 to 0.0508 mm). This clearance is measured between the piston skirt and the cylinder wall. Advances in piston technology have allowed manufacturers to build engines with about half that clearance. This leads to increased efficiency and lower emissions.

Figure 11-57 Always make sure that the markings on the piston and connecting rod are in the correct relationship to each other and they face the correct direction.

Piston Terminology

Many different terms are used to describe the design of a piston; these include:

- **Compression distance (or height)**—The distance from the center of the piston pin bore to the top of the piston.
- **Ring belt**—The area between the top of the piston and the pin bore where the piston rings are installed.
- **Heat dam**—A narrow groove cut in some pistons to reduce heat flow to the top ring groove. During engine operation, the groove fills with carbon and absorbs the heat of combustion.
- **Land diameter**—The diameter of the ring land. On some pistons, the land diameter will be same for each ring; on others it will increase from top to bottom.
- **Land clearance**—The difference between the diameters of the land and the cylinder.
- **Groove root diameter**—The diameter of a piston measured at the bottom of a ring groove. The root diameter of each groove may vary with the type of ring used.
- **Groove protector**—A steel or cast-iron insert placed into the top groove of an aluminum piston to extend the life of the top compression ring.
- **Top groove spacer**—A steel spacer installed above the ring in a reconditioned groove to bring the ring's side clearance within specifications.
- **Piston pin bushing**—Found primarily in cast-iron pistons, this bushing serves as a bearing for the piston pin. It is inserted into the piston pin bore.
- **Major thrust face**—The part of the piston skirt that has the greatest thrust load. This is typically the right side when looking at the engine from the fly-wheel end.
- **Minor thrust face**—The part of the piston skirt that is opposite the major thrust face.
- **Skirt clearance**—The difference between the diameter of the piston skirt diameter and the diameter of the cylinder.
- **Piston skirt taper**—The difference between the diameter of the piston at the top and bottom of the skirt.
- **Piston cam**—The shape of the piston skirt area, which provides correct cylinder wall contact and clearances.

Inspection Each piston should be carefully checked for damage and cracks. Pay attention to the ring lands and the pin boss area. Look for scuffing on the sides

Figure 11-58 Each piston should be carefully checked for scuffing on the sides of the piston.

of the piston (**Figure 11-58**). Light up and down scuffing is normal. Excessive, irregular, or diagonal scuff marks indicate lubrication, cooling system, or combustion problems. Scuffing may also be caused by a bent connecting rod, seized piston pin, or inadequate piston-to-wall clearance. If any damage is evident, the piston should be replaced.

Remove the piston rings. A ring expander should be used to remove the compression rings. Normally the oil control ring can be rolled off by hand. Remove the carbon from the top of the piston with a gasket scraper. Carbon and oil build up in the back part of the groove. This buildup must be removed. The dirt will prevent the rings from seating properly. Clean the grooves of the piston with a groove cleaning tool or a broken piston ring. When doing this, make sure no metal is scraped off. The oil control ring groove has slots or holes. These should also be cleaned. Use a drill bit or small brush. Once the grooves are clean, use a brush and solvent to thoroughly clean the piston. Do not use a wire brush.

Ring side clearance should be measured. Side clearance is the difference between the thickness of the ring and the width of its groove. To measure this, place a new ring in its groove and, with a feeler gauge, measure the clearance between the ring and the top of the groove (**Figure 11-59**). If the clearance is not within the specified range, the piston should be replaced.

Figure 11-59 Ring side clearance should be checked on each piston.

Figure 11-60 The diameter of the piston is measured across specific points on the skirt.

The diameter of the piston should be measured. This measurement is normally taken across specific points on the skirt (**Figure 11-60**). If the diameter is not within specifications, the piston should be replaced. Some engine rebuilders will knurl the skirts if the diameter is slightly less than specifications.

Piston Pins

Piston pins are basically thick-walled hollow tubes. Like the rest of the piston and connecting rod assembly, it is built to be strong and light. Most are made from alloy steel and are plated with chrome, carburized, and/or heat-treated to provide good wear resistance. Piston pins are lubricated by oil fed through

passages in the connecting rods, oil splashing in the crankcase, or spray nozzles in the rods or pistons.

A piston pin fits through the small end of the connecting rod and the piston's pin bore. The way the pin is retained is used to describe it.

- A stationary pin is pressed into the piston. The connecting rod swivels on the pin.
- A semifloating pin is pressed into the connecting rod. The piston swivels on the pin.
- A full-floating pin is able to move or rotate in the piston and connecting rod. The pins are retained by caps, plugs, snaprings, or spring clips inserted in the piston at the ends of the pin. Full-floating pins are the most commonly used.

Inspect the pin boss area on the piston for signs of pin wobble. Then remove the pin to inspect it. With full-floating pins, the retaining clips are removed and the pin pushed out.

A pin press is used to remove and install pressed-fit pins. When installing a piston pin, make sure the piston is facing the correct direction in regard to the connecting rod.

Inspect the pin closely for signs of wear. Full-floating pins should have an even wear pattern. Carefully inspect the pin bore in the piston. Since a piston is made from softer material than the pin, the piston will wear before the pin. If there are signs of uneven wear, suspect a lubrication or connecting rod problem.

Check the fit of the pin. It should move freely through the bores. Also attempt to move the pin up and down in its bores. Any movement means the piston bore or pin is worn. To determine if the bore or pin is worn, measure the diameter of the pin bore. If the bore is not within specifications, replace the piston. Then measure the diameter of the pin. If the pin is not within specifications, replace it. If the piston bore and pin meet specifications, measure the small end bore of the connecting rod (**Figure 11-61**). If the diameter is not within specifications, replace the connecting rod.

Some manufacturers recommend a check of the pin's oil clearance. To do this, subtract the diameter of the pin from the diameter of the piston pin bore. If the oil clearance exceeds specifications, replace the piston and pin. Now subtract the diameter of the pin from the diameter of the connecting rod's small end. If the oil clearance exceeds specifications, replace the connecting rod and/or the pin.

Connecting rods may have a piston pin bushing. Measure the inside diameter of the bushings and compare the reading to specifications. If the bushing

Figure 11-61 The piston pin is measured at a variety of spots and its diameter compared to the ID of the piston's pin bore and the small end of the connecting rod.

is worn or damaged, it should be replaced. The bushing is pressed out of the rod with a pin press. Installing new bushings is also done with a press; some technicians heat the rods and freeze the pins before pressing them in. This makes installation easier. Before applying pressure on the pin, make sure it is set squarely above the bore.

Piston Rings

Piston rings are used to fill the gap between the piston and cylinder wall. The piston rings seal the combustion chamber at the piston. Piston rings must also remove oil from the cylinder walls to prevent oil from entering into the combustion chamber. They also carry heat from the piston to the cylinder walls to help cool the piston.

In most engines, pistons are fitted with two compression rings and one oil control ring. The compression rings are found in the two upper grooves closest to the piston head. The oil ring is fitted to the groove just above the wrist pin. There are many different designs of rings; each has a specific application.

Compression Rings Compression rings are designed to use combustion pressure to force them against the cylinder wall. During the power stroke, the pressure caused by the expanding air-fuel mixture is applied between the inside of the ring and the piston ring groove. This forces the ring into full contact with the cylinder walls. The same force is applied to the top of the ring, forcing it against the bottom of the ring groove. These two actions help to form a tight ring seal.

Common compression rings are made of cast iron, cast iron coated with molybdenum (moly), and

Figure 11-62 (A) A moly-coated compression ring.
(B) A chrome-faced compression ring.

cast iron coated with chrome (**Figure 11-62**). Cast iron offers a durable wear surface and costs less than a moly- or chrome-faced ring. These rings are ideal for normal driving. Moly coatings are quite porous and can hold oil. As a result, moly rings have a very high resistance to scuffing. These rings are used in engines that are run at continuous high speeds or severe load conditions. Chrome also has good resistance to scuffing but does not have the oil retention capabilities of moly. Chrome rings are recommended when driving conditions include frequent travel on dusty or unpaved roads. Chrome is very dense and hard and will push away any dirt that enters the cylinder on the intake stroke. Moly coatings, due to their porosity, will allow dirt to become embedded in a ring's face. Normally, a moly ring is used in the top ring groove with a cast iron or chrome ring in the second groove.

Other face coatings include ceramics, graphite, phosphate, and iron oxide. All coatings are designed to help in the wear-in process. Wear-in is the time required for the rings to conform to the shape and surface of the cylinder wall.

Oil Control Rings Oil is constantly being applied to the cylinder walls. The oil lubricates and cleans the cylinder wall and helps cool the piston. Controlling this oil is the primary purpose of the oil ring. The two common types of oil rings are the segmented oil ring and the cast-iron oil ring. Both are slotted so that excess oil from the cylinder wall can pass through the ring. The piston's oil ring groove is also slotted. Oil

passes through the ring and slots in the piston and returns to the oil sump.

Segmented oil rings have an upper and a lower scraper rail and an expander. The scraper rings are often chrome rings. The expander pushes the two scrapers out against the cylinder wall. During installation, the end gaps of the three pieces must be staggered to prevent oil from escaping into the cylinder.

Installing the Rings

Some engines use low-tension piston rings; make sure the new rings are the correct ones for the engine. Before installing the rings onto a piston, check the rings' end gap. Place a compression ring into a cylinder. Use an upside-down piston to square the ring in the bore. Measure the gap between the ends of the ring with a feeler gauge. Compare the reading to specifications. If the gap exceeds limits, oversized rings should be used. If the gap is less than specifications, the ends of the ring can be filed with a special tool.

The preceding procedure for checking ring gap assumes that all taper and imperfections in the bore have been corrected. If the bore has some taper, the end gap should be checked in the cylinder at the lowest point of piston travel.

Piston ring gap is critical. Excessive gap will allow combustion gases to leak into the crankcase. This is commonly called blowby. Too little clearance can score the cylinder walls as the ends of the rings come in contact with each other as the engine heats up. The gap of the top compression ring allows some combustion pressure to leak onto the second compression ring. This helps the second ring seal.

Apply a light coat of oil on the rings. The oil control ring is installed first. Insert the expander; position the ends above a pin boss but do not allow them to overlap. Then install the rails. Stagger the ends of the three parts. The oil control ring assembly can be installed by hand. If the piston pin is set up into the oil ring groove, an oil ring support must be inserted in the ring groove. The support gives the oil rings a place to sit at the points of the groove where there is no piston material beneath the rings. The support has a dimple to prevent it from rotating around the piston. This keeps the ring gap at the desired spot at all times.

Use a piston expander to install the top and second compression rings (**Figure 11-63**). Install the second ring first. Make sure the rings are installed in the right position. This includes making sure that the correct side of the ring is facing up. Rings have some sort of mark to show which side

Figure 11-63 Use a ring expander to install the compression rings.

should be up. Check the instructions of the ring manufacturer.

INSTALLING PISTONS AND CONNECTING RODS

The piston and connecting rod assemblies are installed next. Check the marks on the connecting rod caps and the connecting rods to make sure they are a match. The bearings for the connecting rods must be the correct size. If the crankshaft has been machined undersize, matching rod bearing inserts must be installed. The size of the bearing inserts is printed on their box and is stamped on the backs of the bearings or color coded.

Snap the bearing inserts into the connecting rods and rod caps. Make sure the tang on the bearing fits snugly into the matching notch. Check the clearance of the connecting rod bearings with Plastigage or a micrometer. Follow the same procedure used to check main bearing clearance. If the clearance is not within specifications, the connecting rod may need to be machined or replaced, or undersized bearings should be installed.

Wipe a coat of clean oil on the cylinder walls. Then install the piston and rod according to the procedure shown in Photo Sequence 8. Remember that connecting rods are numbered for proper assembly. Also make sure that the end gaps of the piston rings are staggered according to the manufacturer's recommendations (**Figure 11-64**) prior to installing the piston assembly.

Coat the crankshaft with clean lubricant or engine oil. After each piston is installed, rotate the crankshaft and check its freedom of movement. If the crankshaft is hard to rotate after a piston has been installed, remove it and look for signs of binding.

Figure 11-64 Install the piston rings onto the piston with a ring expander. Also make sure that the ring end gaps are arranged according to specifications. *Courtesy of Ford Motor Company*

SHOP TALK

Many technicians find it easier to use a wrinkle band ring compressor (**Figure 11-65**) to install pistons. These push the rings into their grooves but do not contact the entire outside of the piston. This makes it easier to push the piston out of the tool.

Figure 11-65 A wrinkle band ring compressor. *Reproduced under license from Snap-on Incorporated. All of the marks are marks of their owners.*

Installing a Piston and Rod Assembly

P8-1 Insert a new piston ring into the cylinder. Use the head of the piston to position the ring so that it is square with the cylinder wall. Use a feeler gauge to check the end gap. Compare end-gap specifications with the measured gap. Correct as needed. Normally, the gaps of the piston rings are staggered to prevent them from being in line with each other. Piston rings are installed easily with a ring expander.

P8-2 Before attempting to install the piston and rod assembly into the cylinder bore, place rubber or aluminum protectors or boots over the threaded section of the rod bolts. This will help prevent bore and crankpin damage.

P8-3 Lightly coat the piston, rings, rod bearings, cylinder wall, and crankpin with an approved assembly lubricant or a light engine oil. Some technicians submerge the piston in a large can of clean engine oil before it is installed.

P8-4 Stagger the ring end gaps and compress the rings with the ring compressor. This tool is expanded to fit around the piston rings. It is tightened to compress the piston rings. When the rings are fully compressed, the tool will not compress any further. The piston will fit snugly but not tightly.

Installing a Piston and Rod Assembly (*continued*)

P8-5 Rotate the crankshaft until the crankpin is at its lowest level (BDC). Then place the piston/rod assembly into the cylinder bore until the ring compressor contacts the cylinder block deck. Make sure that the piston reference mark is in correct relation to the front of the engine. Also, when installing the assembly, make certain that the rod threads do not touch or damage the crankpin.

P8-6 Lightly tap on the head of the piston with a mallet handle or block of wood until the piston enters the cylinder bore. Push the piston down the bore while making sure that the connecting rod fits into place on the crankpin. Remove the protective covering from the rod bolts.

P8-7 Position the matching connecting rod cap and finger tighten the rod nuts. Make sure the connecting rod blade and cap markings are on the same side. Gently tap each cap with a plastic mallet as it is being installed to properly position and seat it. Torque the rod nuts to the specifications given in the service manual. Repeat the piston/rod assembly procedure for each assembly.

Figure 11-66 Measuring connecting rod side clearance.

After the pistons and rods have been installed, check the connecting rod side clearances (**Figure 11-66**). Side clearance is the distance between the crankshaft and the side of the connecting rod. It is measured with a feeler gauge. If the clearance is not correct, the rods may need to be machined or replaced.

INSPECTION OF CAMSHAFT AND RELATED PARTS

After the camshaft has been cleaned, check each lobe (**Figure 11-67**) for scoring, scuffing, fractured surface, pitting, and signs of abnormal wear; also check for plugged oil passages.

Premature lobe and lifter wear is generally caused by metal-to-metal contact between the cam lobe and the lifter bottom due to inadequate lubrication. Wear normally begins within the first few minutes of operation. It is the result of insufficient lubrication.

To check cam lobe wear, measure the lobe height with a micrometer. Measure from the heel to the nose and then again 90 degrees from the original measurement. Record the measurement for each intake and exhaust lobe. Any variation in height indicates wear. Also check the measurements against the manufacturer's specifications.

Measure each camshaft journal in several places to determine if it is worn. If a journal is 0.001 inch

(0.0254 mm) or more below the manufacturer's specifications, it should be replaced.

The camshaft should also be checked for straightness with a dial indicator. Place the camshaft on V-blocks. Position the dial indicator on the center bearing journal and slowly rotate the camshaft. If the dial indicator shows runout (a 0.002-inch [0.0508 mm] deviation), the camshaft is not straight and must be replaced.

If the engine has a worn or damaged camshaft, identify the cause and fix the problem before installing a new camshaft, lifters, and/or followers.

Timing Components

The timing belt or chain and crankshaft/camshaft gears (sprockets) should be inspected and replaced if damaged or worn. A timing gear with cracks, spalling, or excessive tooth wear is an indication of improper **backlash** (either insufficient or excessive). Excess backlash causes the noise as the gears' teeth make violent contact. This overloading causes accelerated tooth wear and breakage. Insufficient backlash can cause the gears to bind. It can also cause high contact forces that can rupture the oil film between the teeth, causing spalling and wear.

Gear backlash is checked with a dial indicator. Check the movement between the camshaft and crankshaft gears at six equally spaced teeth. Hold the gear firmly against the block while making the check. Refer to specifications for backlash limits.

Lifters

When inspecting lifters, carefully check their bottoms and pushrod sockets. Wear should be off the center of the lobe and there should be no signs of edge contact. If they show abnormal wear, scoring, or pitting, they should be replaced. Any lifter that has its contact face worn flat or concave must also be replaced. Lifter bottoms are normally spherical.

Technically, normal lifter wear is referred to as adhesive or galling wear. It results from two solid surfaces (camshaft lobe and lifter face) rubbing on each other. The two surfaces tend to weld together. Fortunately, proper lubrication retards this process. However, excessive loading will accelerate the wear process (**Figure 11-68**). Excessive loading is caused by incorrectly matched valve springs (too much spring pressure), old lifters on a new camshaft, or new lifters on an old camshaft.

Hydraulic lifters should be removed, disassembled, cleaned, and checked. Check the lifter's leakdown with a leakdown tester. Lifter leakdown rate is important. If the lifters leak down too quickly, noisy operation will result. If the lifters do not match

Figure 11-67 A worn lifter and camshaft. Courtesy of Federal-Mogul Corporation

Figure 11-68 The possible wear patterns of a lifter that does not spin in its bore. *Courtesy of TRW, Inc.*

specifications, they should be replaced, along with the camshaft. Never install old flat lifters with a new camshaft or new lifters on a used camshaft.

INSTALLATION OF CAMSHAFT AND RELATED PARTS

Before installing the camshaft and balance shafts with their bearings, coat all parts with assembly lubricant. This lubricant should have an extreme pressure (EP) lubricant rating. This helps prevent scuffing and galling during initial startup. It should also have excellent adhesion to prevent the lubricant from draining off the parts during engine reassembly.

Camshaft Bearings

Although the installation of camshaft bearings can be done after the short block is assembled, it may be easier to align the bearings' oil holes when the crankshaft is not installed. Keep in mind that any engine block that needed to have its main bearing bore alignment corrected due to distortion is likely to have camshaft bearing bore misalignment problems.

OHV cam bearings are normally press-fit into the block or head using a bushing driver and hammer (**Figure 11-69**). The bearing at the rear of the block should be installed first. The camshaft journals may have different diameters, with the smallest being on the rear of the block and each journal being progressively larger.

The new bearing is fit over the tool's expanding mandrel and the tool is set into the block. A guide cone is used to keep the tool centered in the bore. Once the bearing is at the outside of its bore, rotate the bearing to align the oil hole in the bearing with the oil hole in the block.

On blocks with grooves behind the bearings, the bearing should be installed with the oil hole at the 2 o'clock position as viewed from the front. While

Figure 11-69 Cam bearings are normally press-fit into the block or head using a bushing driver and hammer.

holding the centering cone against the outside bore, drive the bearing into its bore. If the cone and tool are allowed to move while inserting the bearings, the bearing can be damaged. While driving the bearings into their bore, be careful not to shave metal off the backs of the bearings. This galling may cause a buildup of metal between the outside of the bearing and the housing bore and result in less clearance. To prevent galling, housing bores should be chamfered.

Camshaft

Wipe off each cam bearing with a lint-free cloth, then thoroughly coat the camshaft lobes, bearing journals, and distributor drive gear (if there is one) with assembly lube. Also lubricate the lifters. Most premature cam wear develops within the first few minutes of operation. Prelubrication helps to prevent this. Use the lubricant recommended by the manufacturer.

The camshaft should be carefully installed to avoid damaging the bearings with the edge of a cam lobe or journal. Keep it straight while installing it. A threaded bolt in the front of the camshaft helps guide the cam in place. An alternative is to install the camshaft while the block rests on its end.

When the camshaft is in place, install the thrust plate and the timing gear. Be sure to align the thrust plate with the woodruff key. Never hammer a gear or sprocket onto the shaft. Heating steel gears helps with installation. Do not heat fiber gears. When installing the gears, be sure to keep the gear square and aligned with the keyway at all times.

Once the shaft is completely in the block, the shaft should be able to be turned by hand. If the cam does not turn, check for a damaged bearing, a nick on the cam's journal, or a slight misalignment of the block journals. If the bearing clearance is too small, some technicians ream away a slight amount of the bearing;

others hone the bearing. Both of these need to be done carefully. The best way to increase the clearance is to cut the camshaft journals on a lathe. Reaming or honing the inside diameter of cam bearings is not recommended because grit may become embedded in bearing surfaces, which will cause shaft wear.

CRANKSHAFT AND CAMSHAFT TIMING

USING SERVICE INFORMATION

Normally, camshaft timing marks are shown in the engine section of a service manual under the heading Timing Belt or Chain R&R.

During most engine rebuilds, a completely new timing assembly is installed. The camshaft drive must be installed so that the camshaft and crankshaft are in time with each other. Both sprockets are held in position by a key or possibly a pin. There are factory timing marks on the crankshaft and camshaft gears or sprockets (**Figure 11-70**). The timing must be positioned according to the manufacturer's instructions.

SHOP TALK

Make sure the timing marks are precisely matched. If the gears are misaligned by one gear tooth, the timing will be off by about 17 degrees.

The chain is installed on the crankshaft gear first, then around the camshaft sprocket. Never wind a

chain onto the gears. Also, a screwdriver, prybar, or hammer should never be used to force a chain into position. Prying or pounding on the chain will damage the links, causing the chain to stretch and fail. Carefully place the entire assembly as a unit onto the shafts by pressing both gears evenly, keeping the keyways aligned. While keeping the gears parallel and aligned, gently tap them in place.

SHOP TALK

There are some OHV engines that are interference engines. If the crankshaft-to-camshaft timing is not correct, the pushrods normally bend when the engine is started. Double-check the alignment.

Some manufacturers recommend additional checks of the camshaft after it has been inserted in the block. These include a check of the clearance between the camshaft gear and the backing plate. This check is made with a feeler gauge. This clearance can often be corrected by repositioning the camshaft gear. Camshaft end play is measured with a dial indicator. As the camshaft is moved back and forth in the block, the indicator will read the amount of movement. Compare this to specifications. End play can be corrected by changing the size of the shim behind the thrust plate or by replacing the thrust plate. Some engines limit the end play with a cam button. A nylon button or Torrington bearing sets on a spring and is installed between the gear and timing chain cover.

Figure 11-70 Camshaft-to-crankshaft and camshaft-to-balance shaft timing marks.

A camshaft is designed to open and close the valves at the correct time. The cam-

shaft, crankshaft, timing gears or sprockets, and timing chains or belts are made to specifications. Those specifications will include a range of acceptable tolerances. This means there is no guarantee that the timing assembly will provide exactly what the camshaft was intended to do. Overall engine performance can be affected by a few degrees of misalignment. Many performance engine builders degree the camshaft to precisely match the position of the camshaft with the crankshaft. Degreeing a cam is highly recommended when installing a performance camshaft. An engine with a properly degreed camshaft will be more efficient than one without a degreed cam.

The exact procedure for degreeing camshafts varies with each engine design. The procedures must be followed exactly as stated by the cam

manufacturer. Degreeing the cam requires a degree wheel, a stable pointer that can be attached to the block, a dial indicator with a mount, a positive TDC stop tool, the specification sheet for the camshaft, and the parts necessary to adjust the mounting of the timing gears. The latter are necessary to position the gears at their correct positions.

Balance Shafts

Balance shafts are serviced in the same way as crankshafts. Each bearing and journal should be cleaned and carefully inspected. All worn or damaged parts should be replaced. The oil clearance of the shafts and bearings should be checked with Plastigage. Place the balance shaft half bearings into the crankcase and then position the balance shaft(s) onto the bearings. Then lay a strip of Plastigage across each journal. Insert the matching bearing halves into the balance shaft housing and tighten the housing bolts to specifications and in the proper sequence. Now remove the housing bolts and housing. Measure the Plastigage at its widest point. Compare the readings to specifications. If the oil clearance is excessive, measure the shaft bore and the shaft(s) journals. Determine the cause of excessive clearances and replace the bearing or balance shaft. Remove the Plastigage completely after measuring.

To install the balance shaft assembly, install the bearings in the crankcase and housing. Apply a light

coat of clean engine oil to the bearings. The shafts need to be properly timed to the crankshaft. On some engines there are two balance shafts; these must be timed to each other, in addition to the crankshaft (**Figure 11-71**). Align the timing marks of the balance shaft(s). Set the shaft(s) into position in the block. Set the housing with bearings over the shafts. Install and tighten the housing bolts. In most cases these bolts should be tightened in two steps and in a prescribed sequence.

Lifters

Before installing the lifters into the lifter bores, generously coat the lifter bores with assembly lube. Coat the lifters and/or followers one at a time as they are being installed. After they have been installed, rotate the camshaft to check for binding or misalignment.

SHOP TALK

Some technicians submerge the hydraulic lifters in clean oil to allow them to fill with oil before installing them.

OIL PUMPS

The oil pump may be located in the oil pan or mounted to the front of the engine (**Figure 11-72**). Its purpose is to supply oil to cool, clean, and lubricate the various moving parts in the engine. The

Figure 11-71 Balance shafts must be timed to each other and the crankshaft.

Figure 11-72 The different ways an oil pump is driven by the crankshaft.

pump is normally driven by the crankshaft and creates suction to draw oil from the oil pan through a strainer. The pump's suction creates pressure that forces the oil through the oil filter to various passages. The oil then returns to the oil pan.

An oil pump does not create oil pressure; it merely moves oil from one place to another. Oil pumps are positive displacement pumps; that is, the amount of oil that leaves the pump is the same amount that enters it. Output volume is proportional to pump speed. As engine rpm increases, pump output also increases. As the oil leaves the pump, it passes through many passages. These passages restrict oil flow. These restrictions are what cause oil pressure. Small passages cause the pressure to increase; larger ones decrease the pressure.

This is why excessive bearing clearances will decrease oil pressure. The increased clearances reduce the resistance to oil flow and, consequently, increase the volume of oil circulating through the engine. This decreased resistance and increased volume lower the pressure of the oil. The ability of an oil pump to deliver more than the required volume of oil is a safety measure to ensure lubrication of vital parts as the engine wears.

Oil pressure is also determined by the viscosity and temperature of the oil. High-viscosity oil has more flow resistance than low-viscosity oil.

Types of Oil Pumps

Oil pumps are driven by the camshaft or crankshaft. In newer engines, the pump is driven by the

crankshaft. Integral pumps are driven directly by the crankshaft, and others are driven by a chain or gear. How the pump is driven is dictated by the location of the pump. Some oil pumps have an intermediate or drive shaft that is driven by a gear on the camshaft. Other pumps are driven by an auxiliary shaft meshed with the camshaft.

The most commonly used oil pumps are the rotor and gear types. A typical **rotor-type pump** (Figure 11-73) has an inner rotor and an outer rotor, which is driven by the inner rotor. The outer rotor always has one more lobe than the inner rotor. When the rotors turn and the rotors' lobes unmesh, oil is drawn into that space. As the rotors continue to turn, the oil becomes trapped between the lobes, cover plate, and top of the pump cavity. It is then forced out of the pump body by the meshing of the lobes. This squeezes the oil out and directs it through the engine. The amount of oil forced out of the pump depends on the diameter and thickness of the pump's rotors.

Gear-type pumps use a drive gear, which is connected to an input shaft, and a driven gear. Both gears trap oil between their teeth and the pump cavity wall. As the gears rotate, oil is forced out as the gear teeth unmesh. The output volume per revolution depends on the length and depth of the gear teeth. Another style of gear-type oil pump uses an idler gear with internal teeth that spins around the drive gear. In this style of pump, often called a crescent or trochoidal type, the gears are eccentric (Figure 11-74). That is, as the larger gear turns, it walks around the smaller one, moving the oil in the space between.

The rotor type moves a greater volume of oil than the gear type because the space in the open lobe of the outer rotor is greater than the space between the teeth of the gears of a gear-type pump.

At times, high-volume pumps are installed. These pumps provide more oil flow. They do not provide higher pressures. High-volume pumps have larger gears or rotors. The increase in oil volume is proportional to the increase in the size of the gears. Gears that are 20% larger will provide 20% more oil volume.

Pressure Regulation

The faster an oil pump turns, the more oil it will move. Therefore, its output pressure increases. A pressure-regulating (relief) valve is used to control the pump's maximum pressure. Excessive oil pressure can lead to poor lubrication due to the oil blowing past parts rather than flowing over them. A pressure regulator valve is loaded with a closely calibrated spring that allows oil to bleed off at a given pressure. When the pressure from the pump reaches

Figure 11-73 A rotor-type oil pump.

Figure 11-74 A gear-type oil pump.

a preset level, a check valve, ball, or plunger unseats and allows the oil to return to either the inlet side of the pump or to the crankcase.

High-pressure oil pumps are basically stock pumps with a stronger relief valve spring. The spring delays the opening of the valve until a higher pressure is reached.

OIL PUMP SERVICE

Many technicians install a new or rebuilt oil pump on each engine they rebuild. Although the oil pump is probably the best lubricated part of the engine, it is lubricated before the oil passes through the filter. Therefore, it can experience premature failure due to dirt or other materials entering the pump. Foreign particles can cause the following:

1. Fine abrasive particles gradually wear the surfaces, causing a reduction in efficiency.
2. Hard particles larger than the clearances can cause scoring as they pass through, finally resulting in seizure.
3. Large particles will physically lock up the pump. Of course, when the pump seizes or locks up, the gears or the drive shaft will be twisted or sheared off.

Inspection

The oil pump should be carefully inspected. Carefully remove the pressure relief valve and note the direction it is pointing to so it can be reinstalled in its proper

position. If the relief valve is installed backward, the pump will not be able to build up pressure. Inspect the relief valve spring for signs of collapsing or wear. Check the tension of the spring according to specifications. Also check the piston for scores and free operation in its bore. Remove the housing bolts, then remove the cover from the housing.

Inspect the gears or rotors and the pump housing for scoring or other damage. Replace the oil pump if any are found.

CAUTION!

Always follow the manufacturer's procedure for servicing or replacing an oil pump.

Mark the gear teeth so they can be reassembled with the same tooth indexing (**Figure 11-75**). The gears and rotors of some pumps are marked by the factory. Once all parts have been removed, clean them and dry them off with compressed air.

SHOP TALK

Use a paint stick or other nonviolent means to mark the gears. If a center punch must be used, file down the raised material around the indent before reassembling the pump. The raised edges may cause interference and wear if they are not removed.

Inspect the pump gears or rotors for chipping, galling, pitting, or signs of abnormal wear. Examine the housing bores for similar signs of wear. If any part of the housing is scored or noticeably worn, replace the pump assembly.

Check the mating surface of the pump cover for wear. If the cover is excessively worn, scored, or scratched, replace the pump. Use a feeler gauge and

Figure 11-75 Mark the gear teeth so they can be reassembled with the same indexing.

Figure 11-76 Measuring the outer rotor with an outside micrometer.

Figure 11-77 Checking clearance between the outer rotor and pump body. *Courtesy of Chrysler LLC*

straightedge to check its flatness. There are specifications for the amount of acceptable warpage. If the cover is excessively warped, replace the pump.

Use a micrometer to measure the diameter and thickness of the rotors (**Figure 11-76**). If these dimensions are less than the specified amount, the rotors or the pump must be replaced.

With rotor pumps, reinstall the rotors into the pump body. Use a feeler gauge to check the clearance between the outer rotor and pump body (**Figure 11-77**). If the housing-to-rotor clearance exceeds specifications, replace the oil pump. If specifications are not available, replace the pump if the measured clearance is greater than 0.012 inch (0.305 mm).

Position the inner and outer rotor lobes so they face each other. Measure the clearance between them with a feeler gauge (**Figure 11-78**). A clearance of more than 0.010 inch (0.2540 mm) is unacceptable and the pump should be replaced. The timing case

Figure 11-78 Measuring clearance between the inner and outer rotor lobes. *Courtesy of Chrysler LLC*

and gear thrust plate might also be worn. Excessive clearance can limit pump efficiency. Replace them as necessary.

On a gear-type pump, measure the clearance between the gear teeth and pump housing. Take several measurements at various locations around the housing and compare the readings. If the clearance at any point exceeds 0.005 inch (0.0762 mm), replace the pump.

On both gear-type or rotor-type oil pumps, make sure the housing surface is clean and free of gasket material before measuring the end clearance of the gears or rotors. Place a straightedge across the pump housing and measure the clearance between the straightedge and gears (**Figure 11-79**). The desired end play clearance should not exceed 0.003 inch (0.1270 mm).

Figure 11-79 Check the housing-to-rotor clearance at the (A) rotors and (B) the housing.

Some manufacturers recommend that liquid thread lock be applied to the pump housing bolts. Always check the service manual before doing this. Install the cover and tighten the bolts to specifications. The gasket that is used to seal the end housing is also designed to provide the proper clearance between the gears and the end plate. Do not substitute another gasket or make a gasket to replace the original one. If a precut gasket was not originally used, seal the end housing with a thin bead of anaerobic sealing material. Turn the input shaft or gear by hand. It should rotate easily. If it does not and the pump passed all tests, replace the pump.

Remove the old oil seal from the oil pump. Install a new seal into the pump housing. Make sure all mating surfaces of the pump are clean, undamaged, and dry.

If the pump uses a hexagonal drive shaft, inspect the pump drive and shaft to make sure that the corners are not rounded. Check the drive shaft-to-housing clearance by measuring the OD of the shaft and the ID of the drive.

The pickup screen (**Figure 11-80**) is normally replaced when an engine is rebuilt. It is important that the pickup is positioned properly. This will avoid oil pan interference and ensure that the pickup is always submerged in oil. When installing the pickup tube, be sure to use new gaskets and seals. Air leaks on the suction side of the oil pump can cause the pressure relief valve to hammer back and forth. Over time, this will cause the valve to fail. Air leaks can also cause oil aeration, foaming, marginal lubrication, and premature engine wear. Care should be taken to make sure that all parts on the suction side of the pump fit tightly and that there is no place for air leakage. Air leakage often comes from cracked seams in the pickup tube.

Figure 11-80 Oil pump pickup. *Courtesy of Chrysler LLC*

INSTALLING THE OIL PUMP

The pump should be primed before assembly. The preferred way to do this is to submerge the pump in clean engine oil. Make sure the inlet port is fully in the oil. Then turn the pump by hand until you see oil flow from the outlet of the pump. The use of heavy lubricants inside the oil pump is not recommended because they do not circulate easily and can cause oil starvation to critical parts when the engine is first started.

Crankshaft-Driven Pump

The installation of a typical crankshaft-driven oil pump is as follows:

1. Install a new oil seal into the pump.
2. Apply liquid gasket evenly to the pump's mating surfaces on the block.
3. Do not allow the gasket material to dry.
4. Coat the lip of the oil seal and the O-rings with oil.
5. Align the inner rotor with the crankshaft.
6. Install and tighten the oil pump.
7. Clean all excess grease on the snout of the crankshaft.
8. Install the oil pickup.

Cam-Driven Pumps

The installation of a typical camshaft-driven oil pump is as follows:

1. Apply a suitable sealant to the pump and block.
2. Make sure that the drive gears are properly meshed and that the drive shaft is seated in the pump.
3. Install the pump to its full depth and rotate it back and forth slightly to ensure proper positioning and alignment through the full surface of the pump and the block machined interface surfaces.
4. Once installed, tighten the bolts or screws. The pump must be held in a fully seated position while installing the bolts or screws.
5. Install the oil pump inlet tube and screen assembly.

Distributor-Driven Pump When installing an older-style, distributor-driven oil pump, position the drive shaft into the distributor socket. The stop on the shaft should touch the roof of the crankcase when the shaft is fully seated. With the stop in position, insert the drive shaft into the oil pump. Install the pump and

shaft as an assembly. Make sure that the drive shaft is seated in the pump drive. Then tighten the oil pump, attaching screws to torque specifications. Install the pump inlet tube and screen assembly.

CASE STUDY

3,000 miles after the shop had rebuilt the engine in a late-model Toyota, the customer returned the car complaining of abnormal noise and vibration coming from the engine. She also said it seemed like the engine had a “miss.”

The technician who did the engine work was experienced and was quite sure he did everything right. The car was taken on a road test and the problem was verified. The noise and vibration varied with engine speed and the engine just did not seem to run right. The vibration seemed to be caused by a loose, damaged, or broken engine mount. So a careful inspection was done. No problem was found with the mounts.

Next, the technician connected a scan tool to see if there were any hints as to why the engine vibrated or had a miss. No codes were retrieved. A thorough inspection was done on everything under the hood. Nothing was obviously broken or disconnected.

He started the engine and looked around it. This is when the potential problem was noticed. The harmonic balancer was wobbling on the shaft. Turning off the engine, he reached down to find that the attaching bolt was loose. He knew he had tightened it during the engine rebuild so the fact that it was loose was a mystery.

He proceeded to tighten the bolt, but checked the torque specifications first. This is when he discovered what he did wrong. The bolt should be tightened to a little over 200 ft.-lb. He knew he did not tighten the bolt that much. To do this, the balancer and crankshaft need to be held stationary while turning the bolt. The balancer, crankshaft sprocket, and woodruff key were inspected. These were not damaged yet. He borrowed the special tool to hold the crank and tightened the bolt. The engine was started and the problem disappeared.

The technician was actually lucky; the wobbling balancer could have caused serious damage to the crankshaft. On this engine, the crank sprocket and harmonic balancer share the same woodruff key. This is the reason for the required bolt torque. The engine miss was caused by the wobbling balancer. The rotation of the crankshaft sprocket is monitored by the crankshaft position sensor, which is located next to the sprocket. The sensor, reacting to the wobbling of the sprocket, sent erratic readings to the engine control module. These unstable signals were enough to cause the miss but were within the normal range so the system did not set a trouble code.

The technician learned once more that following the recommendations of the manufacturer can save time, frustration, and reputation.

KEY TERMS

Babbitt	Leakdown
Backlash	Line boring
Boring bar	Long block
Cam follower	Overlap
Cast	Piston pin
Chamfering	Piston rings
Core plug	Piston skirt
Deck	Plastigage
Dome	Ring lands

Forge	Taper
Full-round bearing	Tappet
Gear-type pump	Total indicator reading (TIR)
Glaze	Valve lifters
Harmonic balancer	Variable valve timing (VVT)
Head	Wrist pin
Hone	
Hypereutectic	

SUMMARY

- The basic short block assembly consists of the cylinder block, crankshaft, crankshaft bearings, connecting rods, pistons and rings, and oil gallery and core plugs. On OHV engines the camshaft and its bearings are also included.
- The cylinder block houses the areas where combustion occurs.
- A properly reconditioned cylinder must be of the correct diameter, have no taper or runout, and have a surface finish such that the piston rings can seal.
- Glaze is the thin residue that forms on cylinder walls due to a combination of heat, engine oil, and piston movement.
- Core plugs and oil gallery plugs are normally removed and replaced as part of cylinder block reconditioning. The three basic core plugs are the disc or dished type, cup type, and expansion type.
- A cam changes rotary motion into reciprocating motion. The part of the cam that controls the opening of the valves is the cam lobe. The closing of the valves is the responsibility of the valve springs.
- Solid valve lifters provide for a rigid connection between the camshaft and the valves. Hydraulic valve lifters do the same but use oil to absorb the shock resulting from movement of the valve train. Roller lifters are used to reduce friction and power loss.
- The camshaft is driven by the crankshaft at half its speed.
- The most common ways to measure cam lobe wear are with a dial indicator or an outside micrometer. The dial indicator test should be conducted with the camshaft in the engine. When using an outside micrometer, the camshaft must be out of the engine.
- Most premature cam wear develops within the first few minutes of operation.
- The crankshaft turns on a film of oil trapped between the bearing surface and the journal surface. The journals must be smooth and highly polished. The flywheel adds to an engine's smooth running by applying a constant moving force to carry the crankshaft from one firing stroke to the next. The flywheel surface may be used as part of the clutch.
- Crankshaft checks include saddle alignment, straightness, clearance, and end play.
- Bearings carry the critical loads created by crankshaft movement. Most bearings used today are insert bearings.
- Maintaining a specific oil clearance is critical to proper bearing operation. Bearings are available in a variety of undersizes.

- Aluminum pistons are light, yet strong enough to withstand combustion pressure.
- Piston rings are used to fill the gap between the piston and cylinder wall. Most of today's vehicle engines are fitted with two compression rings and one oil control ring.
- When installing a piston and connecting rod assembly, various markings can be used to make sure the installation is correct. Always check the service manual for exact locations.
- Connecting rod side clearance determines the amount of oil throw-off from the bearings and measured with a feeler gauge.
- The camshaft is supported in the cylinder block by friction-type bearings, or bushings, which are typically pressed into the camshaft bore in the block or head. Camshaft bearings are normally replaced during engine rebuilding.
- During most engine rebuilds, a new timing assembly is installed. When installing the timing gears, make sure they are aligned to specifications.
- After an engine is rebuilt, a new or rebuilt oil pump is often installed. If the old pump is to be reused, it should be carefully inspected for wear and thoroughly cleaned.

REVIEW QUESTIONS

1. Name the two most common ways to measure cam lobe wear.
2. What is the deck?
3. What is the name of the component in the lubrication system that prevents excessively high system pressures from occurring as engine speed increases?
4. Where does maximum cylinder bore wear occur?
5. What type of valve lifter automatically compensates for the effects of engine temperature?
 - a. hydraulic
 - b. solid
 - c. roller
 - d. all of the above
6. What is the purpose of compression rings?
7. Most pistons used today are made of _____.
 - a. cast iron
 - b. aluminum
 - c. ceramic
 - d. none of the above
8. Core plugs _____.
 - a. are also called expansion plugs
 - b. are used in all cast-iron cylinder blocks
 - c. are a possible source for coolant leaks
 - d. all of the above
9. Which of the following is not of concern when checking a rotor-type oil pump?
 - a. cover flatness
 - b. rotor thickness
 - c. inner rotor-to-outer rotor clearance
 - d. inner rotor-to-pump housing clearance
10. *True or False?* Oil pressure is determined by whether the pump is a gear type or rotor type and by oil clearances, the pump's pressure regulator valve, and oil viscosity.
11. How is the oil pump driven?
12. Each half of a split bearing is made slightly larger than an exact half. What is this called?
 - a. spread
 - b. crush
 - c. both a and b
 - d. neither a nor b
13. The connecting rod journal is also called the _____.
 - a. balancer shaft
 - b. vibration damper
 - c. Plastigage
 - d. crankpin
14. What device in the valve train changes rotary motion into reciprocating motion?
 - a. eccentric
 - b. cam
 - c. bushing
 - d. mandrel
15. Which type of oil ring is slotted so that excess oil can pass through it?
 - a. cast iron
 - b. segmented
 - c. both a and b
 - d. neither a nor b

ASE-STYLE REVIEW QUESTIONS

1. Technician A uses a feeler gauge and straight-edge to determine the pump cover flatness. Technician B uses an outside micrometer to measure the diameter and thickness of the outer rotor. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
2. After installing cam bearings: Technician A checks that the oil holes in the bearings are properly aligned with those in the block by squirting oil into the holes. Technician B checks for proper alignment by inserting a wire through the holes. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
3. Technician A says that a cylinder wall with too smooth a surface will prevent the piston rings from seating properly. Technician B says that a cylinder wall should have a crosshatch honing pattern. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
4. Technician A uses a prybar to stretch the timing chain onto its sprockets. Technician B cools the timing sprockets so that the timing chain will slip over the teeth. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
5. Technician A installs a cup-type core plug with its flanged edge outward. Technician B installs a dish-type core plug with the dished side facing inward. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
6. Technician A uses a micrometer to measure the connecting rod journal for taper. Technician B uses a micrometer to measure the connecting rod journal for out-of-roundness. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
7. Technician A says that piston ring end gaps should be the same for each ring on a piston. Technician B says that piston ring end gaps should be staggered before installing the piston into its bore. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
8. Technician A checks crankshaft end play or end clearance with a feeler gauge. Technician B uses a dial indicator. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
9. When installing an oil pump in an engine: Technician A packs the pump with petroleum jelly. Technician B submerges the pump in clean oil and rotates the pump shaft to fill the pump body. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
10. Technician A says that counterweights are added to crankshafts to offset the weight of the connecting rods and pistons. Technician B says that the connecting rod bearings are fed a fresh supply of oil through holes drilled in the crankshaft. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B

UPPER END THEORY AND SERVICE

OBJECTIVES

- Describe the purpose of an engine's cylinder head, valves, and related valve parts.
- Explain why there are special service procedures for aluminum and OHC heads.
- Describe the types of combustion chamber shapes found on modern engines.
- Describe the different ways that manufacturers vary valve timing.
- Describe the procedures for inspecting valve train parts.
- Explain the procedures involved in reconditioning cylinder heads.
- Explain the procedures involved in reconditioning valve guides, valve seats, and valve faces.
- Explain the steps in cylinder head and valve reassembly.

CYLINDER HEAD

The cylinder head (**Figure 12-1**) is made of cast iron or aluminum. On overhead valve engines, the cylinder head contains the valves, valve seats, valve guides, valve springs, rocker arm supports, and a recessed area that makes up the top portion of the combustion chamber. On overhead cam engines, the cylinder head contains these items, plus the supports for the camshaft and camshaft bearings (**Figure 12-2**).

All cylinder heads contain passages that match passages in the cylinder block. These passages allow coolant to circulate in the head and allow oil to drain back into the oil pan. Oil also moves through some of the passages to lube the camshaft and valve train. The cylinder head also contains tapped holes in the combustion chamber to accept the spark plugs.

The sealing surface of the head must be flat and smooth. To aid in the sealing, a gasket is placed between the head and block. This gasket, called the head gasket, is made of special material that can withstand high temperatures, high pressures, and the expansion of the metals around it. The head also serves as the mounting point for the intake and exhaust manifolds and contains the intake and exhaust ports.

Cylinder head design is one of the most influential factors that affects the overall performance of an engine. The size and shape of the intake and exhaust ports affect the velocity and volume of the mixture entering and leaving the cylinders.

Figure 12-1 A typical late-model cylinder head.

Figure 12-2 An OHC aluminum cylinder head.
Courtesy of Chrysler LLC

Openings in the cylinder head allow coolant to pass through the head. Coolant must circulate throughout the cylinder head to remove excess heat. The coolant flows from passages in the cylinder block through the head gasket and into the cylinder head. The coolant then passes back to other parts of the cooling system.

Ports

Intake and exhaust ports are cast into the cylinder head. One port is normally used for each valve. However, on engines with more than two valves per cylinder, the ports for the intake or exhaust valves may be combined. These ports are called **Siamese ports** (Figure 12-3). With Siamese ports, individual ports around each valve mesh together to form a larger single port that is connected to a manifold. **Cross-flow ports** are used on some engines and have intake and exhaust ports on opposite sides of the combustion chamber. Heads of this design are called cross-flow heads.

Aluminum Heads

Attempts to lower overall engine weight have resulted in many lightweight cylinder head designs. An aluminum head weighs roughly half as much as a cast-iron head. Eliminating anywhere from 20 to 40 pounds of weight is a plus for fuel economy, but these heads bring new concerns for technicians.

Aluminum expands and contracts almost twice as much as cast iron in response to temperature changes. When an aluminum head is mated to an iron block, the difference in thermal expansion between head and block creates a scrubbing stress on the head gasket. Unless the gasket is engineered to take this, leakage and premature gasket failure can result.

The difference in thermal expansion also creates a lot of stress throughout the head. The head wants to expand in all directions as it heats up, but the head bolts keep it from going sideways or lengthwise. The only way it can expand is up, so the head tends to bow up in the middle.

Engines with overhead cams and aluminum heads often have the cam journals machined in the head itself. Aluminum makes a fairly good bearing material.

Figure 12-3 Siamese ports.

It is soft and provides good embedability to foreign particles. But it lacks the support and rigidity of a conventional steel-backed bearing in an iron saddle. Because of this, overhead cam bores experience more flex than their cast-iron counterparts. The result is usually accelerated wear and egg-shaped bores. If the head overheats and warps, alignment through the cam bores is destroyed. In some instances, the misalignment can be so bad that the cam will not turn once the head is unbolted from the engine.

COMBUSTION CHAMBER

The performance of an engine, its fuel efficiency, and its exhaust emissions all depend to a large extent on the shape of the combustion chamber. An efficient combustion chamber must be compact to minimize the surface area through which heat is lost to the engine's cooling system. The point of ignition (the nose of the spark plug) should be at the center of the combustion chamber to minimize the flame path, or the distance from the spark to the furthest point in the chamber. The shorter the flame path, the more evenly the air-fuel mixture will burn.

Manufacturers have designed several shapes of combustion chambers. Before looking at the popular combustion chamber designs, two terms should be defined.

1. **Turbulence** is a very rapid movement of gases. Turbulence causes better combustion because the air and fuel are mixed better.
2. **Quenching** is the mixing of gases by pressing them into a thin area. This area is called the quench area.

Wedge Chamber

In the **wedge-type combustion chamber**, the spark plug is located at the wide part of the wedge (Figure 12-4). The spark travels from the large area in

Figure 12-4 A typical wedge combustion chamber.

the chamber to a smaller one. This allows for rapid and even combustion. At the end of the chamber's wedge is a very narrow area. The **quench area**, also called the squish area, causes the air and fuel to be thoroughly mixed before combustion. The mixture in the quench area is squeezed out at high speed as the piston moves up. This causes turbulence in the chamber. The turbulence breaks down the fuel into small particles and helps mix the air and fuel. Both of these contribute to efficient combustion and reduce the chances of detonation. The turbulence also helps the flame front move evenly throughout the chamber. The wedge-shaped combustion chamber is also called a turbulence-type combustion chamber.

Hemispherical Chamber

The **hemispherical combustion chamber** gets its name from its basic shape. Hemi is defined as half, and spherical means circle. The combustion chamber is shaped like a half circle. This type of cylinder head is also called the **hemi-head**. The piston top forms the base of the hemisphere, and the valves are inclined at an angle of 60 to 90 degrees to each other, with the spark plug positioned between them (**Figure 12-5**).

This design has several advantages. The flame path from the spark plug to the piston head is short, which gives efficient burning. The cross-flow arrangement of the inlet and exhaust valves allows for a relatively free flow of gases in and out of the chamber. The result is that the engine can breathe deeply, meaning that it can draw in a large volume of mixture for the space available and give a high power output.

The hemispherical combustion chamber is considered a nonturbulence-type combustion chamber. The mixture is compressed evenly on the compression stroke. Combustion radiates evenly from the spark plug, completely burning the air-fuel mixture.

Figure 12-5 A typical hemispherical combustion chamber.

Figure 12-6 Shrouding is a restriction in the flow of gases caused by the location of the valves in the combustion chamber.

Figure 12-7 A cylinder head with pentroof combustion chambers.

One of the more important advantages of the hemispherical combustion chamber is that air and fuel can enter the chamber very easily. The wedge combustion chamber restricts the flow of air and fuel to a certain extent. This is called **shrouding**. **Figure 12-6** shows the valve very close to the side of the combustion chamber, which causes the flow of air and fuel to be restricted. Volumetric efficiency is reduced. Hemispherical combustion chambers do not have this restriction.

Pentroof Chamber

Many of today's engines have a **pentroof** combustion chamber. This design is a modified hemispherical chamber. It is mostly found in engines with four valves per cylinder. The spark plug is located in the center of the chamber and the intake and exhaust valves are on opposite sides of the chamber (**Figure 12-7**). Pentroof chambers have a squish area around the entire cylinder.

INTAKE AND EXHAUST VALVES

The intake and exhaust valves are commonly called **poppet** valves (**Figure 12-8**). They tend to pop open and close. When they open, they allow intake air to flow into the combustion chamber or allow the exhaust to leave it. When closed, they must (along with the cylinder head gasket, piston rings, and spark plug) seal the chamber. The heads of the intake and exhaust

Figure 12-8 A poppet valve.

valves have different diameters. The intake valve is the larger of the two. An exhaust valve can be smaller because exhaust gases move easier than intake air.

Valve Construction

Today, most valves are made from special hardened steel, steel alloys, or stainless steel. Other metals are often used in high-performance valves. Heat is an important factor in the design and construction of a valve. The material used to make a valve must be able to withstand high temperatures and be able to dissipate the heat quickly. Most of the heat is dissipated through the contact of the valve face and seat. The heat then moves through the cylinder head to its coolant passages. Heat is also transferred through the valve stem to the valve guide and again to the cylinder head (**Figure 12-9**).

Intake and exhaust valves are typically made with different materials. Intake valves are typically low-alloy steels or heat- and corrosion-resistant high-alloy steels. The alloy used in a typical exhaust valve is chromium for oxidation resistance with small amounts of nickel, manganese, silicon, and/or nitrogen. Heat resistance is critical for exhaust valves because they face temperatures of 1,500°F to 4,000°F (816°C to 2,204°C). Intake valves need less heat resistance because the intake air and fuel tend to cool them. Intake valves also need less corrosion protection because they are not exposed to the corrosive action of the hot exhaust gases.

A valve can be made as a single piece or two pieces. Two-piece valves allow the use of different metals for

Figure 12-9 Valves cool by transferring heat to the liquid passages in the cylinder head.

the valve head and stem. The pieces are spin welded together. These valves typically have a stainless steel head and a high-carbon steel stem. The stems are often chrome plated so the weld is not visible. One-piece valves run cooler because the weld of a two-piece valve inhibits the flow of heat up the stem.

Today's engines require higher quality valves that contain more nickel to withstand the heat. Most exhaust valves and some intake valves have 4% nickel content. The intake valves with high nickel are used in turbocharged engines. Older valves are alloyed with 2% nickel. The alloys used to make valves depend on the intended use and the design of the engine. Newer engines also tend to have lighter valves than what was used in the past. The lighter weight decreases the amount of power lost moving the valves and allows for higher engine speeds.

Stainless Steel Valves Stainless steel is commonly used to make valves. **Stainless steel** is an iron-carbon alloy with a minimum of 10.5% chromium content. Stainless steel does not stain, corrode, or rust as easily as ordinary steel. There are different types of stainless steels used to make valves. Austenitic stainless steels contain a maximum of 0.15% carbon, a minimum of 16% chromium, and nickel and/or manganese to give it strength and improve its heat resistance. Stainless steel is nonmagnetic.

Inconel Valves An alloy that is being used by many manufacturers is Inconel. Inconel has a nickel base with 15% to 16% chromium and 2.4% to 3.0% titanium. This alloy is normally used in high-temperature applications and has good oxidation

and corrosion resistance. Inconel is difficult to machine; therefore, Inconel valves are replaced when they are deformed or damaged.

Stellite Valves Another alloy that is used in high-temperature applications is stellite. **Stellite** is an alloy of nickel, chromium, and tungsten and is nonmagnetic. Stellite is a hard-facing material that is welded to valve faces and stems. It may also be used on the stem tip for added wear resistance. It comes in various grades depending on the mix of ingredients that are used in the alloy. This alloy has high resistance to wear, corrosion, erosion, abrasion, and galling. Stellite is available in many different grades, which are determined by the materials used in the alloy.

Sodium Filled Some exhaust valves have a hollow stem. The hollow section of the stem is partially filled with sodium (**Figure 12-10**). Sodium is a silver-white alkaline metallic substance that transfers heat much better than steel. At operating temperatures, the sodium becomes a liquid. When the valve opens, the sodium splashes down toward the head and absorbs heat. Then as the valve moves up, the sodium moves away from the head and up the stem. The heat absorbed by the sodium is then transferred to the guide where it moves to the coolant passages in the head. Sodium-filled valves should not be machined.

WARNING!

Never cut open a sodium-filled valve. Sodium will burn violently when it contacts water.

Titanium Valves Titanium alloys are added to valves to lighten them. Some high-performance engines have titanium valves. These valves dissipate heat well, are durable, and are very light. A titanium valve weighs less than half of a comparable steel valve.

Figure 12-10 Some exhaust valves are partially filled with sodium to help cooling.

Figure 12-11 The parts of a typical valve.

Ceramic Valves Ceramic valves are being tested for future use. Ceramic materials weigh less than half of what a comparable size steel valve weighs and can withstand extreme temperatures without weakening or becoming deformed.

Valve Terminology Valves (**Figure 12-11**) have a round head with a tapered face used to seal the intake or exhaust port. This seal is made by the **valve face** contacting the valve seat. The angle of the taper depends on the design and manufacturer of the engine. The distance between the valve face and the head of the valve is called the **margin**. The **valve stem** guides the valve during its up-and-down movement and serves to connect the valve to its spring through its valve spring retainers and keepers. The keepers are fit into a machined slot at the top of the stem, called the valve keeper groove. The stem moves within a **valve guide** that is either machined into (integral type) or pressed into the head (insert type).

Valve Stems

Little oil passes through the clearance between the stem and valve guide. Therefore, the surfaces of the guide and the stem are designed to minimize friction. Valve stems have two common types of coating to prevent wear and reduce friction: chrome plating and

black nitriding. In addition to these coatings, the tips of the stem are hardened or stellite to resist damage from the constant hammering they face as the stems are pushed open.

Chrome-plated stems help prevent valve stem scuffing and galling and provide protection against wear during initial engine starts when no oil is present on the valve stem. Chrome coating is also widely used on high-performance valves. The thickness of the chrome plating can vary from 0.0002 to 0.001 inch (0.0051 to 0.0254 mm).

Many foreign manufacturers use a black nitride coating rather than chrome plating on the valves. Black nitride is applied to the entire valve, not just the stem. The finish of the surface is smoother than chrome; therefore, less friction is produced by the stem. The nitride coating protects the stems against scuffing and wear.

Valve Seats

The valve seat (**Figure 12-12**) is the area of the cylinder head contacted by the face of the valve. The seat may be part of the casting and machined in the head (integral type) or it may be pressed into the head (insert type). Insert seats are always used in aluminum cylinder heads. They are also used to replace damaged integral seats.

Valve seats provide a sealing area for the valves. They also absorb the valve's heat and transfer it to the cylinder head. Seats must be hard enough to withstand the constant closing of the valve. Due to corrosive products found in exhaust gas, seats must be highly resistant to corrosion. When the head is made of cast iron, it has integral seats because cast iron meets those requirements. Cast iron is also used to make seat inserts. Most are induction hardened. These are hardened through electromagnetism, which heats the surface of the seat.

Many late-model engines with aluminum heads have sintered powder metal (tungsten carbide) seats. Powder metal seats are harder and more durable than cast-iron seats.

Figure 12-12 Valve seats.

Figure 12-13 (A) Integral and (B) removable valve guides.

Valve Guides

Valve guides support the valves in the head and prevent the valves from moving in any direction other than up and down. The inside diameter of a guide is machined to provide a very small clearance with the valve stem. This close clearance is important for the following reasons:

- It keeps oil from being drawn into the combustion chamber past the intake valve stem during the intake stroke, and it keeps oil from leaking out to the exhaust port when the pressure in the exhaust port is lower than the pressure in the crankcase.
- It keeps exhaust gases from leaking into the crankcase area past the exhaust valve stems during the exhaust stroke.
- It keeps the valve face in perfect alignment with the valve seat.

Valve guides can be cast integrally with the head, or they can be removable (**Figure 12-13**). Removable or insert guides are press-fit into the head. Aluminum heads are fitted with insert guides. Guides are made from materials that provide low friction and can transfer heat well. Cast-iron guides are mixed or coated with phosphorus and/or chrome. Bronze alloys are also used. These may contain some aluminum, silicon, nickel, and/or zinc.

Valve Spring Retainers and Oil Seals

The valve assembly is completed by the spring, retainer, and seal. An oil seal is placed over the top of the valve stem. The seal acts like an umbrella to keep oil from running down the valve stem and into the combustion chamber. The valve spring, which keeps the valve in a normally closed position, is held in place by the retainer. The retainer locks onto the valve stem with two wedge-shaped parts that are called **valve keepers**. **Figure 12-14** shows the components that make up a valve spring assembly.

Figure 12-14 Valve assembly with spring, retainer, seals, and keepers.

Valve Rotators Some engines are equipped with retainers that cause the exhaust valves to rotate. These rotators prevent carbon from building up between the valve face and seat. Carbon buildup can hold the valve partially open, causing it to burn.

Valve Springs

A valve spring closes the valve and maintains valve train contact during valve opening and closing. Some engines have one spring per valve. Others use two or three springs. Often the second or third spring is a flat spring called a **damper spring**, which is designed to control vibrations. To dampen spring vibrations and increase total spring pressure, some engine manufacturers use a reverse wound secondary spring inside the main spring.

Low spring pressure may allow the valve to float during high-speed operation. Too much pressure will cause premature valve train or camshaft lobe wear and can also lead to valve breakage.

Other Valve-Related Parts

Other parts are associated with the valves.

Rocker Arms Rocker arms change the direction of the cam's lifting force. As the lifter and pushrod move upward, the rocker arm pivots at its center point. This causes a change in direction on the valve side and pushes the valve down. Rocker arms also allow the valve to open farther than the actual lift of the cam lobe. This is done by having different distances from the pivot point to the ends of the rocker arm. The difference in length from the valve end of the rocker arm and the center of the pivot point (shaft or stud) compared to the pushrod or cam end of the rocker arm and the pivot point (shaft or stud) is expressed as a ratio. Usually, rocker arm ratios range from 1:1 to 1:1.75. A ratio larger than 1:1 results in the valve opening farther than the actual lift of the cam lobe.

Figure 12-15 The camshaft in this setup rides on a rocker arm that has a hydraulic lash adjuster.

Chapter 8 for an explanation of rocker arm ratios.

The camshaft in some OHC engines rides directly on the rocker arm. One end of the rocker arm fits over a cam follower or lifter and the other end is over the valve stem (**Figure 12-15**). Often OHC cylinder heads have a complex arrangement of rocker arms (**Figure 12-16**). Other OHC engines have no rocker arms and the camshaft rides directly on top of the valves.

Rocker arms are made of stamped steel, cast aluminum, or cast iron. Cast adjustable rocker arms are attached to a rocker arm shaft that is mounted to the head by rocker arm brackets (**Figure 12-17**). Cast-iron rockers are used in large, low-speed engines. They almost always pivot on a common shaft. Aluminum rockers, on the other hand, are generally used on high-performance applications and pivot on needle bearings to reduce friction.

Some domestic engines are equipped with a stamped steel rocker arm for each valve. The rocker arm is mounted to a stud that is either pressed or threaded into the cylinder head and must be replaced if worn, bent, broken, or loose. On some engines, the studs are drilled for an oil passage to the rocker arms.

Pushrods Pushrods are the connecting link between the rocker arm and the valve lifter. Pushrods transmit cam action to the valves. Often the pushrods have a

Figure 12-16 This arrangement has three rocker arms per valve. Courtesy of American Honda Motor Co., Inc.

Figure 12-17 Rocker arm shaft assemblies. Courtesy of Chrysler LLC

hole in the center to allow oil to pass from the hydraulic lifter to the rocker arm assembly (**Figure 12-18**). Some engines use pushrod **guide plates** to limit the side movement of the pushrods.

Chapter 11 for a discussion on camshafts.

Cam Followers Found on some OHC engines, cam followers are cups that sit on top of the valve assembly.

Figure 12-18 Most pushrods have a hole through the center to allow oil flow from the hydraulic lifter to the rocker arm assembly.

Figure 12-19 Many OHC cylinder heads are machined to accept one or two camshafts above the valves and have bearing caps to secure the camshaft.

bly. They provide a larger surface for the cam lobes to move the valves. Some followers have a hydraulic unit that fits under the cup to maintain proper valve clearance. Others require periodic adjustment. Most use metal shims between the cup and cam lobe. To adjust valve clearance, a shim with a different thickness is inserted.

Camshaft Bearings The camshaft is part of the cylinder head assembly in all OHC-type engines. The unit that holds the camshaft(s) may be a separate unit bolted to the cylinder head or the camshaft's bore is machined into the upper part of the head. In the most common design, the cylinder heads are machined to accept one or two camshafts and have caps that secure the camshaft (**Figure 12-19**).

Multivalve Engines

Many newer engines use multivalve arrangements. One of the first cars to use four valves per cylinder as a way to enhance gas flow and increase horsepower was the 1918 dual-valve Pierce Arrow.

The basic idea behind using more than one intake and/or exhaust valve is simple—better efficiency. To improve efficiency, engineers need to improve the flow in and out of the combustion chamber. In the past, this was attempted by making the valves larger and by changing valve timing. Larger valves allowed more air in and more exhaust out, but the bigger valves weighed more and therefore required stronger springs to close them. The stronger springs held the valves closed tighter but required more engine power to open them. Also, when an engine is running at low speeds, the air moving past a large valve has a lower

velocity than it would have if it flowed past a small valve. This reduces engine torque at low engine speeds.

Although two small valves weigh as much or more than one valve, each valve weighs less and, therefore, the spring tension on each is less. This means less power is required to open them. Also, the velocity of the air in and out at low engine speeds is quicker than it would be with large valves.

Today, multivalve engines can have three (**Figure 12-20**), four (**Figure 12-21**), or five valves per

Figure 12-20 An engine with two spark plugs, two intake valves, and one exhaust valve for each cylinder.

Figure 12-21 Typical layout for a cylinder with four valves.

Figure 12-22 This five-valve per cylinder arrangement has three intake valves and two exhaust valves.
Courtesy of Chrysler LLC

cylinder (**Figure 12-22**). The most common arrangement is four valves per cylinder with two intake and two exhaust valves. All multivalve engines have cross-flow heads.

Using two intake and one or two exhaust valves increases the volume of the intake and exhaust ports. Therefore, more air can move in or out of the cylinder. This results in a more complete combustion, which reduces the chances of misfire and detonation. It also results in better fuel efficiency, cleaner exhaust, and increased power output. Two smaller valves have less mass than one big one, so mechanical inertia is reduced, making a higher engine speed possible before valve float occurs.

VARIABLE VALVE TIMING

Changing valve timing in response to driving conditions improves driveability and lowers fuel consumption and emission levels. There are many different variable valve timing (VVT) systems used on today's engines. Many systems only vary the timing of the intake camshaft, some vary the timing of the intake and exhaust valves, and a few vary the timing and lift of all the engine's valves.

VVT systems are either staged or continuously variable designs. Most staged systems allow two different valve timing and lift settings. Continuously variable systems alter valve timing whenever operating conditions change. Continuously variable systems change the phasing or timing of a valve's duration (**Figure 12-23**). These systems provide a wider torque curve, reduction in fuel consumption,

Advancing	Retarding
Begins Intake Event Sooner	Delays Intake Event
Lengthens Valve Overlap	Shortens Valve Overlap
Builds More Low-End Torque	Builds More High-RPM Power
Decreases Piston to Intake Valve Clearance	Increases Piston-to-Intake Valve Clearance

Figure 12-23 The effects of changing intake valve timing.

improved power at high speeds, and a reduction in hydrocarbon and NO_x emissions. On some engines, VVT has eliminated the need for an exhaust gas recirculation (EGR) valve.

Cylinder Deactivation

Cylinder deactivation works by keeping the intake and exhaust valves constantly closed in a group of the engine's cylinders. This decreases the working displacement of the engine and provides an increase in fuel economy and reduced emissions. The systems are designed to make the deactivation and activation of the cylinders unnoticeable to the driver. This is accomplished by controlling the fuel injectors, ignition timing, throttle opening, and valve timing. The exact system used for cylinder deactivation varies with the engine design and the manufacturer.

OHC engines typically have a pair of rocker arms at each valve. One of the rocker arms rides on the camshaft lobe and the other works the valve. When the two rocker arms are locked together, the valve moves according to the rotation of the camshaft. To disable a cylinder, the rocker arms are unlocked. The rocker arm on the cam lobe continues to work but does not transfer its movement to the other. The locking device is simply a pin that moves in response to oil pressure. A solenoid, controlled by the PCM, directs oil pressure to the pin.

Honda's variable cylinder management (VCM) system is an example of this. This system is based on the i-VTEC variable valve control system, which is a staged valve timing system.

OHV engines also use oil pressure to deactivate the cylinders. High pressure is sent to the hydraulic lifters to collapse them. The lifters then follow the cam lobes but do not move the pushrods and rocker arms. There are two ways this is done. Chrysler's multidisplacement system (MDS), found in some V8 engines, has an oil circuit controlled by four solenoids and eight unique hydraulic roller lifters. When conditions dictate that the vehicle does not need all eight cylinders, the PCM energizes the solenoids. Oil pressure is sent to the lifters. The pressure pushes on a small pin

Figure 12-24 The lifter used in Chrysler's multidisplacement system. When the pin in the center is moved, the piston inside the lifter is disconnected from the lifter body. *Courtesy of Chrysler LLC*

in the lifters (**Figure 12-24**). As the pin moves, the piston inside the lifter is disconnected from the lifter body. The lifter body continues to move with the cam lobe but no motion is passed on to the rocker arms.

General Motors' displacement on demand (DoD) system, now called active fuel management (AFM), uses two-stage switching lifters. The lifters have an inner and outer body connected by a spring-loaded pin. High oil pressure, sent by solenoids, collapses the spring and the two lifter bodies disconnect.

Staged Valve Timing

Most staged valve timing systems switch between two or more different camshaft profiles based on operating conditions. An example of this is Honda's VTEC system used on multivalve engines. The camshaft has three lobes for each pair of intake valves. The third lobe is shaped for more valve lift and different open and close times (**Figure 12-25**). There is a rocker arm

LOBE	INTAKE	EXHAUST
1st	1.1692 in. (29.700 mm)	1.1771 in. (29.900 mm)
2nd	1.4003 in. (35.568 mm)	1.4054 in. (35.699 mm)
3rd	1.4196 in. (36.060 mm)	

Figure 12-25 The size of the cam lobes for one cylinder for Honda's three-stage VTEC system.

Figure 12-26 The synchronizing pin is controlled by oil pressure and locks the rocker arms together.

over each of the three lobes. At low engine speeds, only the second lobe's rocker arms move the valves. At high speed, a solenoid valve sends pressurized oil through the rocker shaft to a piston in the outer rocker arms (**Figure 12-26**). This pushes the piston partly into the center rocker arm, locking the three rocker arms together. The valves now open according to the shape of the third lobe. When the solenoid valve closes, a spring pushes the pistons back into the outer rockers, and the engine runs with normal valve timing.

This system has been modified to include VCM, also called the cylinder idling system, on some engines. This system is used on Honda's hybrid to increase the regenerative braking capabilities of the vehicle and to minimize fuel consumption. The system allows normal and high-output valve timing, plus cylinder idling at all or some cylinders. The system is based on three rocker arms per valve. One rocker arm is used to activate the valve. The other two ride on camshaft lobes. A hydraulically controlled pin connects and disconnects the rocker arms. When there is no connection between the two cam-riding rockers and the valve rocker, the cylinder is idling or deactivated. There are three separate oil passages leading to the pin. As the pressure moves through a passage, it moves the pin. The PCM controls a spool valve that directs the pressurized oil to the appropriate passage. It also controls solenoids that control the amount of pressure.

Operation In a typical system, when the brake pedal is released and the accelerator depressed, the vehicle moves by both electric and engine power. At this time the engine is running in the economy mode with the

valves opening by the low lift camshaft profile. When the driver is maintaining a very low cruising speed, the engine shuts off and the electric motor powers the car by itself. During this time, the engine's rocker arms are not opening the valves. During acceleration from a low speed, the engine runs in the economy mode. During heavy acceleration, the engine runs in its high-output mode and the electric motor assists the engine. During deceleration, the motor begins to work as a generator and the engine's valves close and remain closed. This allows for maximum regenerative braking and reduces fuel consumption.

Continuously Variable Timing

To provide continuously variable valve timing, camshafts are fitted with a **phaser**. The phaser is mounted where a timing pulley, sprocket, or gear would be (**Figure 12-27**). The phaser allows camshaft-to-crankshaft

Figure 12-27 The phaser assembly on the intake camshaft of a Lexus' VVT-i engine. Courtesy of Toyota Motor Sales, U.S.A., Inc.

Figure 12-28 An exploded view of a phaser.

timing to change while the engine is running. Phasers can be electronically or hydraulically controlled. In a hydraulically controlled system, oil flow is controlled by the PCM. Electronic systems rely on stepper motors. A few engines have electronic/electric intake cam phasers with hydraulic exhaust cam phasers.

A phaser assembly is a sealed unit comprised of a hub and an internal vane assembly (**Figure 12-28**). Around the hub is a timing gear that is connected by chain or belt to the crankshaft. The vane assembly is attached to the camshaft. As the vane assembly moves, the phasing of the camshaft changes. At the base of the hub are oil ports. Oil from control solenoids enters and exits through these ports. When the PCM determines a need to change valve timing, oil is sent to the correct port. The pressurized oil then pushes on the vanes and causes a change in valve timing. Changes in valve timing are made by changes in oil pressure on either side of the vane.

On a few engines, phasers are connected to the intake and exhaust camshafts, therefore altering the timing of both. It is important to realize that by altering the timing of both the intake and exhaust valves, valve overlap is also changed. Ford's 5.4-liter Triton V8 engine has a single camshaft in each cylinder bank. The engine also has VVT. This means the timing of the intake and exhaust valves are shifted in equal amounts. When more low-speed torque is required, the PCM orders earlier valve opening and closing.

When more high-speed power is needed, the cam timing is retarded.

Prius VVT-i System The engine in a Prius, like other hybrid vehicles, operates on the Atkinson cycle. However, it also runs with a conventional four-stroke cycle. The switching between the two cycles is done by valve control. Toyota's VVT-i system is reprogrammed to allow the intake valve to close later for the Atkinson cycle. The Atkinson cycle effectively reduces the displacement of the engine and is in operation when there is low engine load.

The VVT-i system is controlled by the PCM. The PCM adjusts valve timing according to engine speed, intake air volume, throttle position, and water temperature. In response to these inputs, the ECM sends commands to the camshaft timing oil control valve (**Figure 12-29**). A change in oil pressure changes the position of the camshaft and the timing of the valves. The camshaft timing oil control valve is duty cycled by the ECM to advance or retard intake valve timing.

Valvetronic System

Many BMW engines have infinitely variable intake and exhaust valve lift and timing control. Valvetronic is used with variable intake and exhaust valve timing to regulate the flow of air into the cylinders by controlling valve lift. By doing this, the engine has no need for a throttle plate. In fact, this is one of the biggest advantages of the

Figure 12-29 The spool valve in the camshaft timing oil control valve is duty cycled by the PCM. This allows oil pressure to be applied to the advance or retard side of the phaser. *Courtesy of Toyota Motor Sales, U.S.A., Inc.*

system. A throttle plate has a tendency to rob the engine of power, especially at low engine speeds.

In conventional engines the throttle plate regulates the flow of incoming air, while the lift and duration of the intake valve remain constant. During low speeds, the throttle plate is almost totally closed and blocks most of the air available for the cylinders. This results in a pumping loss. **Pumping loss** is a term used to describe the difficulty a piston has in moving air into the cylinder and moving it out on the exhaust stroke. Pumping losses are a major reason why engines consume a disproportionately large amount of fuel in city driving.

Valvetronic solves this problem by controlling the flow of incoming air at the intake valves. This system uses a conventional camshaft with a secondary eccentric shaft and a series of levers and roller followers that are activated by a stepper motor (**Figure 12-30**). A

Figure 12-30 The secondary eccentric shaft and stepper motor assembly for the Valvetronic system. *Courtesy of BMW of North America, LLC*

computer changes the phase of the eccentric cam to change the action of the valves.

At high engine speeds the system dials in maximum lift, opening the ports for maximum flow to guarantee rapid filling of the cylinder (**Figure 12-31**). At low engine speeds, the system reverts to minimal valve lift (**Figure 12-32**). This reduces the amount of

Figure 12-31 The position of the eccentric shaft to provide maximum lift in a Valvetronic system. *Courtesy of BMW of North America, LLC*

Figure 12-32 The position of the eccentric shaft to provide minimum lift in a Valvetronic system. *Courtesy of BMW of North America, LLC*

air entering the cylinder. The action of the valves becomes the engine's throttle plates.

Other VVT Systems

A unique setup for controlling intake and exhaust valve timing and lift relies on a conventional camshaft, which is ground for high performance, with hydraulic lifters fitted with ultra-high-speed valves to bleed off the fluid. The PCM changes the pressure in the lifter to delay valve openings, change valve duration, or prevent valves from opening. A solenoid is used to control the flow of oil into a piston in each lifter that effectively determines the tappet's height.

Another design uses pressurized oil to allow a four-valve-per-cylinder engine to operate as a three-valve engine at low speeds. At high speeds the engine uses the four valves. Below 2,500 rpm, each intake valve follows a separate camshaft lobe. The primary valve opens and closes normally, while the secondary intake opens just enough to keep the engine running smoothly. As the engine reaches 2,500 rpm, the PCM allows pressurized oil to move small pins that lock each pair of rocker arms together, causing both intake valves to follow the normal cam lobe. When the engine slows down, the pressurized oil is bled off and the pin releases, separating the two rocker arms.

The Volvo 3.2-liter engine uses a mix of staged and continuously variable cam timing. It is also unique in the fact that the camshaft is driven at the flywheel end of the engine. The camshaft's phasers are chain-driven. The lift of the intake valves varies with the cam lobe that the rocker arms are riding on. This change is done with a locking pin controlled by oil pressure.

CYLINDER HEAD DISASSEMBLY

On some OHC engines, the rocker arms must be removed before the head is disassembled. If the camshaft rides directly above the rocker arms, use the appropriate spring compressor and depress the valve enough to pull the rocker arm out (**Figure 12-33**). Some have the rocker arms mounted on a separate shaft. The ends of the rocker arms do not directly contact the valves; rather a bridge rocker arm is used. The bridge rocker arm assembly is also mounted on a shaft. To remove these rocker arms, both shafts are unbolted (**Figure 12-34**).

On all OHC engines, the camshaft must be removed before the cylinder head can be disassembled. Follow the specified order for loosening the camshaft bearing caps. Keep the caps in the order they were on the head. Also, draw a diagram of the arrangement of the cam follower assemblies and mark each part. This will ensure that each part is returned to the same position.

Figure 12-33 On some OHC heads, the valve springs must be slightly compressed to remove the rocker arms.

Figure 12-34 Rocker arm assemblies should always be removed by following the prescribed order for loosening the mounting bolts.

Figure 12-35 Measure valve spring height before disassembling the cylinder head. *Courtesy of Ford Motor Company*

Measure the installed spring height for each valve and record it (**Figure 12-35**). This measurement will be needed during reassembly. To remove the valves from the cylinder head, use a valve spring compressor. First, select a socket that fits over the valve tip and onto the retainer. Tap the socket with a plastic mallet to loosen the valve keepers. Adjust the jaws of the compressor so they fit securely over the spring

retainers. Compress the valve springs just enough to remove the keepers (**Figure 12-36**).

Next, remove the valve oil seals and the valves. Keep all assemblies together according to the cylinder they were in. If a valve does not pass through its guide, the tip might be mushroomed or peened over and have a ridge around it. Do not drive the valve through the guide. It could score or crack the valve guide or head. Raise the stem and file off the ridge until the stem slides through the guide easily (**Figure 12-37**).

Figure 12-36 With a spring compressor, compress the springs just enough to remove the keepers.

Figure 12-37 A mushroomed valve tip should be (A) filed before removing the valve from (B) its guide.

Figure 12-38 Checking a cylinder head for warpage.

Inspection of Head

Cylinder heads should be carefully inspected after they are cleaned. Any severe damage to the sealing and valve areas indicates that the head should be repaired or replaced. Also use the appropriate method for detecting any and all cracks. Check the heads for dents, scratches, and corrosion around water passages.

As engines undergo heating and cooling cycles over their life span, certain parts tend to warp. This is especially true of cylinder heads. By using a precision straightedge and feeler gauge, the amount of warpage can be measured. The surface should be checked both across the head as well as lengthwise (**Figure 12-38**). In general, maximum allowable deformation is 0.004 inch (0.1016 mm). Check the manufacturer's recommendations for the maximum allowable warpage for the engine you are working on. Many manufacturers recommend head replacement if it is warped beyond allowable limits. Also check the flatness of the intake and exhaust manifold mounting surfaces.

Aluminum Cylinder Heads

WARNING!

Aluminum cylinder head bolts should never be loosened or tightened when the metal is hot. Doing so may cause the cylinder head to warp due to torque changes.

Figure 12-39 Lightweight aluminum heads are prone to cracking. This can lead to a recessed exhaust valve seat.

Aluminum heads experience fair amounts of thermal expansion, which can lead to cracking. The most crack-prone areas are usually the areas around the valve seats (**Figure 12-39**). High-combustion temperatures and the constant pounding of the valve against its seat often cause cracking between the intake and exhaust seats or just under the exhaust seat.

Aluminum has another drawback—**porosity**. The casting process sometimes leaves microscopic pores in the metal, which can weep oil or coolant. In most instances, the problem is only cosmetic and does no real harm. But the customer may not agree. To the customer, a wet spot on the outside of a cylinder head looks like a leak.

Aluminum heads should be carefully checked for dents, scratches, and corrosion around water passages. Also, they should be checked for warpage. Warpage in an aluminum cylinder head is usually the result of overheating (low coolant, uneven coolant circulation within the head, a too lean fuel mixture, and incorrect ignition timing). For aluminum heads, the maximum allowable warpage is less than it is for cast-iron heads.

Always check the cylinder head thickness and specifications to be sure that material can be safely removed from the surface. Some manufacturers do not recommend any machining; rather they require head replacement if cylinder head flatness is not within specifications. Aluminum heads can be straightened through the use of heat and special clamping fixtures. However, some manufacturers do not recommend this.

Alignment of the cam bores in an OHC head should be checked with a straightedge and feeler gauge. If the bores are more than 0.002 to 0.003 inch (0.0508 to 0.0762 mm) out of alignment, corrective action is required.

Valves

Each valve face should be carefully checked for evidence of burning (**Figure 12-40**). Also check the entire

Figure 12-40 Severely burnt valves.

Figure 12-41 Parts of a valve that should be checked during your inspection.

valve for signs of wear or distortion (**Figure 12-41**). Replace any valves that are badly burned, worn, or bent. Also discard any valve that is badly burned, cracked, pitted, or shows signs of excessive wear. Carefully examine the facings on the stem. If the plating is flaking or chipped, the valve should be replaced.

Examine the backside of the intake valves. A black oily buildup in the neck and stem area indicates that oil is entering the cylinder through the intake valve (**Figure 12-42**) or valve guide seats. Measure the margin left on the valve. Valves that cannot be refaced without leaving at least a $\frac{1}{32}$ -inch (0.79 mm) valve margin should not be reused. Reusable valves are cleaned by soaking them in solvent, which will soften the carbon deposits. The deposits are then removed with a wire buffing wheel. Once the deposits are removed, the valve can be resurfaced.

When replacing a valve, make sure the new one is an exact replacement for the original. This includes the stem diameter, stem height, head diameter, and

Figure 12-42 An oily soot or heavy carbon buildup on the back of the valves indicates bad valve seals.

the material used to make the valve. The first three items can be measured and compared. However, it is not easy to identify the metals used for the valve. Replacement valves should be made from the same or a better alloy than the original valve. A good starting point to identifying the metal is to see if it is magnetic or not. Stainless steel is nonmagnetic, while carbon steel is magnetic.

Valve Seats

Valve seats should be checked for damage, cracks, burning, and deterioration. Also, check insert seats for looseness in their bores. This is done by prying on the inside of the seat. With moderate pressure there should be no movement. If any damage is found on the seat, a new insert seat can be installed. If an integral seat is damaged, the area around it will need to be cut out and an insert seat installed. If the seat appears to have sunk too deeply in its bore, it needs to be replaced.

A seat should also be replaced if its valve was broken or bent. This may have been caused by the seat not being concentric with the guide. This causes the valve stem to flex every time the valve closes.

Retainers and Keepers

Valve spring retainers and valve keepers hold the valve spring and valve in place. The retainer holds the spring in line with the valve stem. A worn retainer will allow the spring to move away from the centerline of the valve. This will affect valve operation because spring tension on the valve will not be evenly distributed. Each retainer should be carefully inspected for cracks, since a cracked retainer may result in serious damage to the engine. The inside shape of most retainers is a cone that matches the outside shape of the keepers.

Figure 12-43 Common valve spring designs.

This must be a good fit in order to secure the keepers in their grooves on the valve stem. Both the retainers and keepers should be inspected for wear and damage. They should be replaced if a defect is found.

The valve stem grooves should match the inside shape of the keepers. Some valves have multiple keeper grooves. Others have only one. All of the valve stem grooves should be inspected for damage and fit by inserting a keeper in them.

Valve Rotators

When valves are refaced or replaced, the rotators should be replaced because they cannot be accurately inspected. Whether or not they rotate by hand is no indication of how they actually function. Uneven wear patterns on the valve stem tip are an indication that the rotators are not working properly.

Valve Springs

The valve spring assemblies (**Figure 12-43**), including the damper springs, should be checked for signs of cracks, breaks, and damage. The high stresses and temperatures imposed on valve springs during operation cause them to weaken and sometimes break. Rust pits will also cause valve spring breakage. To determine if the spring can be reused, the following tests should be performed.

Freestanding Height Test Line up all the springs on a flat surface and place a straightedge across the tops. Measure from the table top to the straightedge. Throw away any spring that is not within specifications.

Spring Squareness Test A spring that is not square will cause side pressure on the valve stem and abnormal wear. To check squareness, set a spring upright against a square (**Figure 12-44**). Turn the spring until a gap appears between the spring and the square. Measure the gap with a feeler gauge. If the gap is more than 0.060 inch (1.524 mm), the spring should be replaced.

Open/Close Spring Pressure Test The procedure for checking valve spring open and close spring pressure

Figure 12-44 Spring squareness test.

Figure 12-45 Valve spring height terminology: (A) free height, (B) valve closed spring height, and (C) valve open spring height.

is given in Photo Sequence 9. Close pressure guarantees a tight seal. The open pressure overcomes valve train inertia and closes the valve when it should close. Spring pressure specifications are listed according to spring height (**Figure 12-45**). Any spring that does not meet specifications should be replaced.

When making any change in hopes of increasing horsepower, especially a cam change, do not forget to install stiffer valve springs. Higher-tension springs will help keep the lifters in contact with the cam lobes and overcome the increased momentum of the valves and the valve train during high engine speeds. Match the springs' tension with the engine. Excessive spring tension is not good. It can put too much stress on the cam lobes, lifters, rocker arms, and so on, and cause them to wear prematurely. Always follow the recommendations of the camshaft manufacturer when replacing valve springs.

INSPECTION OF THE VALVE TRAIN

When inspecting the valve train, each part should be carefully checked. Use the following guidelines when inspecting the components.

Figure 12-46 Various forms of timing belt wear.

Timing Belts

Most often, the belt is replaced when the engine or head is rebuilt. Stripped/broken belt failure is commonly due to insufficient tensioning, extended service life, abusive operation, or worn tensioners. Most manufacturers recommend timing belt replacement every 60,000 miles. Loose timing belts will jump across the teeth of the timing sprockets, causing shearing of the belt teeth. Check for cord separation and cracks on all surfaces (**Figure 12-46**) of the belt. Also check for evidence of exposure to oil or water. Both can cause deterioration of the belt. If the belts are contaminated or damaged, they should be replaced.

On many engines, severe engine damage will result from a broken timing belt. When a timing belt breaks, the camshaft no longer turns, but the crankshaft continues to rotate through inertia. When the camshaft stops, the valves stay where they were when the belt broke. This means some of the valves are open. As the pistons continue to move, they can strike the open valves. This results in bent or broken valves and/or damaged piston domes.

SHOP TALK

The condition of a rubber timing belt can frequently be checked by the fingernail test. Press your fingernail into the hardened backside of the belt. If no impression is left, the belt is too hard; this is caused by overheating and aging.

Measuring and Fitting Valve Springs

P9-1 Prior to installing the valve and fitting valve springs, all other head work should be completed.

P9-2 Install the valve into its proper valve guide.

P9-3 Install the valve retainer and keepers. Without the spring, these must be held in place.

P9-4 While pulling up on the retainer, measure the distance between the bottom of the retainer and the spring pad on the cylinder head with a divider.

P9-5 Use a scale to determine the measurement expressed by the divider.

P9-6 Compare this measurement with the specifications given in the service manual for installed spring height.

Measuring and Fitting Valve Springs (continued)

P9-7 If measured installed height is greater than the specifications, a valve shim must be placed under the spring to correct the difference.

P9-8 Spring tension must be checked at the installed spring height; therefore, if a shim is to be used, insert it under the spring on the valve spring tension gauge.

P9-9 Compress the spring into the installed height by pressing down on the tester's lever.

P9-10 The tension gauge will reflect the pressure of the spring when compressed to the installed or valve closed height. Compare this reading to the specifications.

P9-11 Now compress the spring to the open height specification. Use the rule on the gauge or a scale to measure the compressed height.

P9-12 Compare this reading to specifications. Any pressure outside the pressure range given in the specifications indicates that the spring should be replaced. After the tension and height have been checked, the spring can be installed on the valve stem.

Figure 12-47 The timing chain on some engines should be measured in sections while it is being stretched.

Timing Chains

Each drive chain should be inspected and replaced if it is damaged. The length of the chain should also be checked. Some manufacturers recommend measuring the entire length of the chain and comparing that to specifications. The chains on other engines should be measured in sections while they are being stretched. To do this, pull the chain with the specified tension. Then measure the length of the specified number of chain links (**Figure 12-47**). This measurement is taken at three random sections of the chain. The average length is then compared to specifications. The chain should be replaced if it is not within specifications.

Belt Idler Pulley

All idler pulleys should be rotated by hand. They are okay if they move smoothly. The pulley should also be checked for signs of lubricant leakage. Check around the seal. If leakage is evident, the idler should be replaced.

Tensioners

The tensioners of belt and chain drive systems should be checked. There are many types of tensioners used in today's engines; refer to the service information for the correct inspection procedure. Check the surface of the tensioner's pulley. It should be smooth and have no buildup of grease or oil (**Figure 12-48**). Most belt tensioners should also be checked for signs of lubricant leakage. Check around the seal. If any damage or leakage is evident, the tensioner should be replaced.

The action of a belt tensioner should be checked. Make sure the spring is free to move the tensioner pulley. If the tensioner spring is defective, replace the tensioner. On plunger-type tensioners, hold the tensioner with both hands and push the pushrod strongly against a flat surface. The pushrod should not move. If it does, replace the tensioner. Measure the distance the pushrod extends from the housing. Compare that

Figure 12-48 A timing belt tensioner assembly.

Figure 12-49 Timing chain components.

distance to specifications. If this measurement is not within specifications, replace the tensioner.

Chain drive systems have a variety of dampers and guides in addition to a tensioner (**Figure 12-49**). The dampers and guides should be checked for wear. In most cases, their width is measured and compared to specifications. If they are worn, they should be replaced. Again, there are different types of chain tensioners, each with a unique inspection procedure. The plunger in ratchet-type tensioners should be able to be smoothly moved out by hand but should not be able to be pushed in by hand.

Gears and Sprockets

All timing gears and sprockets should be carefully inspected. A gear with cracks, spalling, or excessive wear

on the tooth surface is an indication of improper backlash. All damaged or worn gears should be replaced. The oil pump, camshaft timing, crankshaft timing, and balance shaft gears and sprockets on some engines are measured with the drive chain wrapped around the individual gears. The diameter of the gear with the chain around it is measured with a vernier caliper. The caliper's jaws must connect the chain's rollers while doing this. If the diameter is less than specifications, the chain and gear or sprocket should be replaced.

Cam Phasers

Camshaft phasers are used in most VVT systems. The action of a hydraulic phaser can be checked while it is attached to the camshaft. Clamp the camshaft in a soft-jawed vise. Attempt to rotate the timing gear on the phaser. If it moves, the phaser must be replaced. Next, cover all of the oil ports on the phaser with electrical tape except the advance port (**Figure 12-50**). Using an air nozzle with a rubber tip, apply the specified air pressure to the exposed port (**Figure 12-51**). The timing gear should move counterclockwise. When the air is released, the timing gear should move clockwise. This check should be conducted several times and the timing gear should move smoothly. This process is then repeated at the retard port. In this case all ports, except the retard port, are sealed.

Cam Followers and Lash Adjusters

Overhead cam follower arm and lash adjuster assemblies should be carefully checked for broken or

severely damaged parts. If pads are used to adjust the valve lash, the cups and the shim pads should also be carefully checked. A soft shim will not hold the valve at its correct lash; therefore, the hardness of each shim should be checked. You can do this by placing a shim on the base circle of the camshaft and, with your hand, press down on the shim. You should feel no give.

Rocker Arms

Inspect the rocker arms for wear, especially at points that contact the valve stem and pushrod. Make sure the oil feed bore in each rocker arm is clear and not plugged with dirt. The fit between a rocker arm and its shaft is checked by measuring the outside diameter of the shaft and comparing it to the inside diameter of the rocker arm (**Figure 12-52**). Excessive clearance requires replacement of the rocker arm or the rocker shaft, or both. Another wear point that should be checked is the pivot area of the rocker arm. Also check for loose mounting studs and nuts or bolts. Replacement press-in studs are available in standard sizes and oversizes. The standard size is used to replace damaged or worn studs and the oversizes are used for loose studs.

Excessive wear on the valve pad occurs when the rocker arm repeatedly strikes the valve tip in a hammer-like fashion. This is caused by excessive valve lash due to improperly adjusted valves or bad hydraulic lifters. Worn rocker arm valve pads can also be caused by poor lubrication. Although a cast rocker arm can be resurfaced, a stamped nonadjustable rocker arm that is worn must be replaced.

Figure 12-50 Location of the advance port on a camshaft phaser.

Figure 12-51 The action of the phaser is checked by applying air to the port and observing the timing gear.

Figure 12-52 Measure the inside diameter of the rocker arm and check for an out-of-round condition.

Honda's Variable Cylinder Management Rocker Arms

Honda uses oil pressure and two sets of rocker arms to alter cam timing and to deactivate cylinders. This system has unique inspection and service procedures. When inspecting them, keep all parts in order so they can be installed in their original location. Measure the outside diameter of each rocker shaft at the location of the first rocker arm. Then measure the inside diameter of the rocker arm. The difference between the two is the clearance. This clearance should be compared to specifications. Repeat this procedure for each rocker arm and shaft. If the clearance is beyond specifications, replace the shaft and all over-tolerance rocker arms. If one rocker arm needs replacement, all of the rocker arms on that shaft should be replaced.

Next, inspect the synchronizing pistons in the rocker arms. Slide them into the rocker arms; they should move smoothly. If they do not or are damaged, the rocker arm assembly should be replaced. The rocker arm oil control solenoid has a filter. This should be checked and replaced if it is clogged.

Pushrods

During inspection, some pushrods may be found to have a groove worn in the area in which they pass through the cylinder head, and some may have tip wear. Also, the ends of the pushrods should be checked for nicks, grooves, roughness, or signs of excessive wear. All damaged pushrods should be replaced. Hollow pushrods should be thoroughly cleaned so there are no blockages in the bore.

Check the straightness of each of the pushrods. Bent pushrods can be caused by incorrect valve timing, valve sticking, or improper valve adjustment. Bent or broken pushrods can also be caused by the use of incorrect valve springs or if the valve's installed height is less than specified. Also, insufficient valve-to-piston clearance can cause a collision between the valve and piston at high engine speeds.

Pushrods can be visually checked for straightness while they are installed in the engine by rotating them with the valve closed. With the pushrods out of the engine, they can be checked for straightness by rolling them over a flat surface such as a surface plate. If a pushrod is not straight, it will appear to hop as it is rolled. However, the most accurate way to check for straightness is by using a dial indicator.

Camshaft and Bearings

The camshafts in most OHC engines are secured to the cylinder head by bearing caps. Some ride on split bearings, whereas others ride on a machined surface in the cylinder head. The bearings or bearing surface

Figure 12-53 Camshafts should be checked for straightness.

should be carefully inspected for signs of unusual wear that may indicate an oiling or bore alignment problem. If the engine is equipped with camshaft bearings, they are normally replaced during engine rebuilding. If the camshaft bore is damaged, the cylinder head is normally replaced.

Each lobe of the camshaft should be checked for wear, scoring, scuffing, fractured surface, pitting, and signs of abnormal wear. Also check for plugged oil passages.

The camshaft should also be checked for straightness. Place the camshaft on V-blocks. Place a dial indicator on one of the middle journals. Rotate the camshaft and watch the dial indicator (**Figure 12-53**). Compare the highest reading to specifications. If the measurement exceeds specifications, replace the camshaft. With a micrometer, measure the height of each cam lobe and the diameter of each journal. If the readings do not meet specifications, replace the camshaft. Repeat this procedure on each camshaft.

SERVICING CYLINDER HEADS

Service to the cylinder head can involve many different procedures. These procedures vary with the metal used to make the head and the design of the engine. Always refer to the appropriate service information from the manufacturer before starting any work on the head.

Crack Repair

Common locations of cracks in a cylinder head include: between the spark plug bore and the valve seat, between the valve seats, around the valve guides, and in the exhaust ports. In most cases, a cracked head should be replaced. However, some cracks can be effectively repaired. Crack repair is normally done by specialty shops.

It is important to keep in mind that most cracks are caused by something other than a defect in the head. The cause of the cracking needs to be identified and corrected. No matter what caused the crack, the crack needs to be repaired if the head is reused. Crack repair is done by the cold process of pinning or the hot process of welding.

Furnace Welding Crack Repairs Furnace welding is considered the best way to repair cracks in a cast-iron head. To furnace weld, the head is first preheated in an oven. This minimizes thermal shock when the flame of a welding torch contacts the head. After the crack has been filled with metal, the head is allowed to slowly cool before it is used.

Flame Spray Welding Flame spray (powder) welding is also used to repair cast-iron heads. This process uses nickel-based powders and a special torch to fill the crack.

Repairing Aluminum Heads Defects in aluminum heads are commonly found as:

- Cracks between the valve seat rings
- Cracks in coolant passages
- Cracks across the main oil artery
- Detonation damage inside the combustion chamber
- Melted or deformed metal in the chamber
- Coolant-related metal erosion

In many cases, these problems result in head replacement. However, some heads are repairable. **Tungsten inert gas (TIG)** welding is the preferred way to repair aluminum heads (**Figure 12-54**). Welding aluminum is often considered difficult because it welds differently than iron or steel. When exposed to air, aluminum forms an oxide coating on

the surface that helps protect the metal against corrosion. The oxide layer makes welding difficult because it interferes with fusing and weakens the weld. A TIG welder prevents the formation of the oxide by bathing the weld with inert gas (normally argon).

Pinning Cracks Pinning is commonly used to repair small accessible cracks in cast-iron and aluminum heads. Pins are used only when the metal is thick enough to secure the pins. Pinning is done with a drill, tap, and tapered or straight pins. Holes are drilled into the ends of the crack to keep it from spreading, then holes are drilled at various overlapping intervals along the length of the crack. After they are installed, the pins are peened to seal the surface. A sealant is not required when tapered pins are used; however, it must be applied over the repair area when straight pins are used.

Resurfacing Cylinder Heads

There are three reasons for resurfacing the deck surface of a cylinder head:

1. To make the surface flat so that the gasket seals properly
2. To raise the compression ratio
3. To square the deck to the main bores

Heads that are deformed beyond specifications must be replaced or resurfaced.

The refinished surface should not be too smooth. It must be rough enough to provide “bite” but not enough to cause a poor seal and leakage. For proper head gasket seating, the finish should have shallow scratches and small projections that allow for gasket support and sealing of voids.

WARNING!

Before operating any surfacing machine, be familiar with and follow all the cautions and warnings given in the machine's operation manual. Also, when operating these machines, wear safety glasses, goggles, or a face shield.

Figure 12-54 TIG welding an aluminum head.

Belt Surfacers Belt surfacers resemble belt sanders. These machines are easy to set up and operate. An operator merely places the part to be surfaced on the belt. A restraint rail helps keep the part positioned (**Figure 12-55**). Some machines have air-operated holddown fixtures.

Figure 12-55 (A) A typical belt sander and (B) how it is used.

Figure 12-56 Milling an aluminum cylinder head.

Resurfacing quality depends on operator skill and factors such as belt condition, machine horsepower, and the holddown pressure applied.

Milling Machines **Milling** machines cut away thin layers of metal to create a level, properly finished surface (**Figure 12-56**). Cutters remove up to 0.050 inch (1.27 mm) per pass. Both rough and finish cuts are usually made to create the desired finish.

Broaching Machines **Broaching** machines use an underside rotary cutter or broach. A block, cylinder head, or intake manifold is held in an inverted position as the broach passes underneath.

Surface Grinders Surface grinders use a grinding wheel to remove metal stock (**Figure 12-57**). They set up and operate similarly to milling machines.

Figure 12-57 A surface grinder.

Stock Removal Guidelines

The amount of stock removed from the head gasket surface must be limited. Excessive surfacing can lead to problems in the following areas.

Compression Ratio After resurfacing a cylinder head, the combustion chamber will be smaller. This will raise the compression ratio. How much depends on how much metal was removed from the surface and the type of chamber. A good rule of thumb is that when 0.010 inch (0.2540 mm) has been removed from the head, the compression ratio will increase by about 0.141:1 to 0.20:1.

To determine if the compression ratio increased too much, it may be necessary to measure the volume of the combustion chamber. Measuring the volume is called **cc-ing** the head. This is done with the valves and spark plugs installed. The cylinder head is mounted upside down, and a glass or plastic plate is installed over the combustion chamber. A graduated container called a burette is used to fill the combustion chamber with thin oil. The oil is poured through a hole in the plate, as shown in **Figure 12-58**. The

Figure 12-58 CC-ing a cylinder head to find the combustion volume.

amount of oil required to fill the chamber is equal to the volume (in cubic centimeters) of the chamber. The measured volume is compared to specifications.

If the chamber volumes are unequal, individual chambers can be matched by grinding the valve seats to sink the valves and by grinding and polishing metal from the combustion chamber surface. Either method can be used to equalize the volumes and adjust them to specifications.

On some engines, a thicker head gasket can be used to decrease the compression after the head has been resurfaced. There can be as much as 0.040-inch difference between various types and brands of gaskets. For instance, changing from a soft-faced to a steel or copper shim gasket can increase the compression ratio by as much as 0.50:1.

Valve Timing On many OHC engines, it is necessary to restore the distance between the camshaft and crankshaft gears after the head has been resurfaced. Special shims are used to raise the cylinder head, which raises the camshaft. If 0.030 inch (0.7620 mm) was removed from the head surface, the camshaft must be moved up 0.030 inch (0.7620 mm). If this is not done, valve timing will be altered.

Piston/Valve Interference When the block or head is surfaced, the piston-to-valve clearance becomes less. To prevent the valves from making contact with the piston, a minimum of 0.070 inch piston-to-valve clearance is recommended.

Misalignment Removing metal from the head or block also causes valve tips, rocker arms, and push-rods to be positioned closer to the camshaft. This causes a change in rocker arm geometry and can cause hydraulic lifters to bottom out.

Also, on V-type engines, the mountings for the manifolds will be lower. This can present a sealing problem with the intake manifold. Also, the ports might be mismatched and manifold bolts might not line up. In order to return the intake manifold to its original alignment, metal on the sealing surfaces of the manifold must be removed.

SHOP TALK

If one cylinder head on a V-type engine is resurfaced, the other one must be cut so equal amounts of metal are removed from each head.

RECONDITIONING VALVES

Whenever the valves have been removed from the cylinder head, the valve heads and valve seats should be resurfaced. The most critical sealing surface in the valve train is between the face of the valve and its seat when the valve is closed. Leakage between these surfaces reduces the engine's compression and power and can lead to valve burning. To ensure proper seating of the valve, the seat area on the valve face and seat must be the correct width, at the correct location, and concentric with the guide. These are accomplished by renewing the surface of the valve face and seat.

Valve grinding or refacing is done by machining a fresh, smooth surface on the valve faces and stem tips. Valve faces suffer from burning, pitting, and wear caused by opening and closing millions of times during the life of an engine. Valve stem tips wear because of friction from the rocker arms or actuators. Valve tips are machined after the valve face is refinished.

Valve Face

Valves can be refaced on either grinding or cutting (**Figure 12-59**) machines. Although grinding machines are common, they should not be used on some late-model valves. The manufacturer may recommend cutting the valve face. The process for grinding or cutting a valve face is much the same. However, grinding uses a stone and cutting uses a hardened blade.

USING SERVICE INFORMATION

Specifications for valve angles are listed in the engine specifications section of a service manual.

Figure 12-59 Cutter-type valve resurfacer. Courtesy of Neway Manufacturing, Inc.

Before using a stone to grind a valve face, it should be dressed (Figure 12-60). A special diamond cutting tip is passed by the stone to clean it and provide an even surface. Place the valve as deeply as possible into the machine's chuck. This eliminates stem flexing while pressure is exerted on the valve. Set the angle of the stone or cutting bit to the desired angle.

SHOP TALK

Many manufacturers recommend that the angle of the valve seat and face have an interference angle of 1 degree. This provides a good seal through a wedging effect. The 1-degree difference can be made at the valve face or seat, or split between the two.

Take light cuts (Figure 12-61) using the full width of the grinding wheel. Make sure coolant is flowing

Figure 12-60 Before grinding a valve, the stone should be dressed.

Figure 12-61 Take light cuts on the valve using the full width of the grinding wheel.

Figure 12-62 A sharp edge on the valve face is not recommended.

over the contact point between the valve face and the grinding wheel. Remove only enough metal to clean up the valve face. A knifelike edge will heat up and burn easily or might cause preignition (Figure 12-62). The width of the edge of a valve head between the top of the valve and the edge of the face is the valve margin. As a general rule, it is not advisable to grind a valve face to a point where the margin is reduced by more than 25% or to where it is less than 0.045 inch (1.143 mm) on the exhaust and 0.030 inch (0.7620 mm) on the intake valves.

After grinding, check valve head runout. Use a dial indicator on the valve margin and rotate the valve while it is still in the chuck. Valve runout should not exceed 0.002 inch (0.0508 mm) TIR. The face should not show any chatter marks or unground areas. After grinding, examine the valve face for cracks. Sometimes fine cracks are visible only after grinding. Sometimes they occur during grinding due to inadequate coolant flow or excessive wheel pressure.

CAUTION!

Always wear eye protection when operating any type of grinding equipment.

Valve Stem

Removing metal from the valve face and/or seat will set the valve deeper into the port. As a result, more of the valve stem extends from the other side of the head. If the stem height is greater than that specified by the manufacturer, the valve stem tip must be ground down to bring the overall height of the stem back into specs. In some cases, if the stem height is excessive, the valve and/or valve seat must be replaced. Valve stem installed height is measured from the valve spring pad on the cylinder head to the top of the valve (Figure 12-63). When the installed height is excessive, valve train geometry can be thrown off or there can be valve lash problems.

Figure 12-63 Measuring valve stem installed height.

The valve tip is ground so that it is exactly square with the stem. Because valve tips have hardened surfaces up to 0.030 inch (0.7620 mm) in depth, only 0.010 inch (0.2540 mm) can be removed during grinding. If more than 0.010 inch (0.2540 mm) is removed from the tip, the valve must be replaced. Follow the manufacturer's specifications for the allowable limits. After the tip has been ground, the edges should be chamfered. This is done by setting the valve at a specified angle to the grinding or cutting tool. The valve is then rotated until the entire edge is smooth.

VALVE GUIDE RECONDITIONING

Valve guide problems can be lumped into one of three basic categories: inadequate lubrication, valve geometry problems, and wrong valve stem-to-guide clearance.

Inadequate lubrication can be caused by oil starvation in the upper valve train due to low oil pressure, obstructed oil passages, improper operation of push-rods, and using the wrong type of valve seal. Insufficient lubrication results in stem scuffing, rapid stem and guide wear, possible valve sticking, and ultimately valve failure due to poor seating and overheating.

Geometry problems include an incorrectly installed valve height, off-square springs, and rocker arm tappet screws or rocker arms that push the valve sideways every time it opens. This causes uneven guide wear, leaving an egg-shaped hole. The wear leads to increased stem-to-guide clearance, poor valve seating, and premature valve failure.

A certain minimum amount of clearance is needed for lubrication and thermal expansion of the valve stem. Exhaust valves require more clearance than intakes because they run hotter. Clearance should also be close enough to prevent a buildup of varnish and carbon deposits on the stems, which could cause sticking. Insufficient clearance, however, can lead to rapid stem and guide wear, scuffing, and sticking,

which prevents the valve from seating fully. This, in turn, causes the valve to run hot and burn.

Guide Wear

The amount of valve guide wear can be measured with a ball (small-bore) gauge and micrometer. Insert and expand the ball gauge at the top of the guide. Lock it to that diameter, remove it from the guide, and measure the ball gauge with an outside micrometer. Repeat this process with the ball gauge in the middle and the bottom of the guide (**Figure 12-64**). Compare your measurements to the specifications for valve guide inside diameter. Then compare your measurements against each other. Any difference in reading shows a taper or wear inside the guide.

Another way to check for excessive guide wear is with a dial indicator. The accuracy of this check is directly dependent on the amount the valve is open during the check. Some manufacturers specify this amount or provide special spacers that are installed over the valve stem to ensure the proper height. Attach the dial indicator to the cylinder head and position it so the plunger is at a right angle to the valve stem being measured (**Figure 12-65**). With the plunger in

Figure 12-64 Valve guide wear can be measured with a small-hole gauge and a micrometer.

Figure 12-65 Checking for valve guide wear with a dial indicator.

contact with the valve head, move the valve toward the indicator and set the dial indicator to zero. Now move the valve from the indicator. Observe the reading on the dial while doing this. The reading on the indicator is the total movement of the valve and is indicative of the guide's wear. Compare the reading to specifications.

If the clearance is too great, oil can be drawn past both the intake and exhaust guides. Though oil consumption is more of a problem with sloppy or worn intake guides because the guides are constantly exposed to vacuum, oil can also be pulled down the exhaust guides by suction created in the exhaust port. The outflow of hot exhaust creates a venturi effect as it exits the exhaust port, creating enough vacuum to draw oil down a worn guide (**Figure 12-66**).

Because it retains oil well, the antiseize and antiwear characteristics of bronze allow a bronze guide to last two to five times longer than a cast-iron guide.

Knurling

Knurling is one of the fastest ways to restore the inside diameter (ID) of a worn valve guide. The process raises the surface of the guide ID by plowing tiny furrows through the surface of the metal (**Figure 12-67**). As the knurling tool cuts into the guide, metal is raised

Figure 12-66 (A) Worn intake guides allow the intake vacuum to suck oil down the guide, and (B) worn exhaust guides can do the same.

Figure 12-67 Knurling restores the inside diameter (ID) dimensions of a worn valve guide by raising the inside surface of the guide by plowing tiny furrows through the surface of the metal.

or pushed up on either side of the indentation. This effectively decreases the ID of the guide hole. A bur-nisher is used to press the ridges flat and is then used to shave off the peaks of these ridges to produce the proper-sized hole and restore the correct guide-to-stem clearance.

One of the main advantages of knurling is that it does not change the centerline of the valve stem. Knurling also allows a rebuilder to reuse the old valve if wear is within acceptable limits, helping to reduce rebuilding costs. In spite of its speed and simplicity, knurling is not a cure for badly worn guides.

Reaming and Oversized Valves

Reaming increases the guide hole size to take an oversize valve stem or restores the guide to its original diameter after installing inserts or knurling.

When reaming, limit the amount of metal removed per pass. Always reface the valve seat after the valve guide has been reamed and use a suitable scraper to break the sharp corner (ID) at the top and bottom of the valve guide.

The advantage of reaming for an oversized valve is that the finished product is totally new. The guide is straight, the valve is new, and the clearance is accurate. The use of oversized valve stems is generally considered to be superior to knurling. Yet, like knurling, it is relatively quick and easy. The only tool required is a reamer. Its use is limited to heads in which the guides are not worn beyond the limits of the available oversize valves.

Thin-Wall Guide Liners

Thin-wall guide liners (**Figure 12-68**) are often inserted into guides to restore them. They provide the benefits of a bronze guide surface. They can be used in integral and replaceable guides. It is faster, easier, and cheaper than installing new guides in heads with replaceable or integral guides, and it maintains guide centering with respect to the seats.

Figure 12-68 A thin-wall valve guide liner.

Phosphor-bronze or silicon-aluminum-bronze are used to make the liners. They are designed for a 0.002- to 0.0025-inch (0.0508 to 0.0635 mm) press-fit. A tight fit is necessary for proper heat transfer and to prevent the liner from working loose.

The original guides are bored to the required diameter for the liner. The liner is then pressed into the bore. It is important to note that some liners are not precut to the length of the original guide. When this is the case, the liner should be cleanly cut or milled to the correct length before installing it. After installation, guide-to-valve stem clearance should be checked and corrected by reaming or knurling.

Valve Guide Replacement

Replacing the valve guide is a repair option. However, pressing out the old guides and installing new ones can be difficult on aluminum heads. Cracking the head or galling the guide hole is always a risk.

Integral Guides To replace integral guides, bore the old guide out. The bore should allow for an interference fit of about 0.002 inch (0.0508 mm). Most technicians freeze the guides before attempting to install them. Lubricate the guide and press or drive it into the bore in the head. It is important to keep the guide straight while it is being installed.

Occasionally, the new guide will not be concentric with the valve seat. Install a new seat to correct the problem, and check the concentricity of the valve seat with a concentricity gauge (**Figure 12-69**).

Insert Guides To press out an old valve guide, place a proper-sized driver so that its end fits snugly into the guide. The shoulder on the driver must also be slightly smaller than the OD of the guide. Use a heavy ball peen hammer to drive the guide out of the cylinder head.

This procedure should be done with care. There is always the danger of breaking the guide or damaging the guide bore in the head. Cast-iron guides in particular have a tendency to gall aluminum heads. If the bore

becomes damaged, it must be rebored and an oversized guide installed. To help prevent these problems, freeze and lubricate the guides before installation. Also, use a press and the correct driver to install them. Keep the guide aligned in its bore and press straight down, not at an angle. If one end of the guide is cut at an angle, make sure the angle is properly placed within the valve port.

Valve Guide Height Guide height is important to avoid interference with the valve spring retainer. The manufacturer's specifications give the correct valve guide installed height, but it is wise to measure the height of the old guides and use this as a reference. As each guide is installed, the installed height should be measured. As each guide is installed, insert a valve. Check for any stem interference.

RECONDITIONING VALVE SEATS

To ensure proper seating of the valve, the valve seat must be the correct width (**Figure 12-70**), in the correct location on the valve face, and concentric with the guide (less than 0.002-inch [0.0508 mm] runout).

The ideal seat width is $\frac{1}{16}$ inch for intake valves and $\frac{3}{32}$ inch (2.38 mm) for exhaust valves. This width ensures proper sealing and heat transfer. However, when an existing seat is refinished to make it smooth and concentric, it also becomes wider.

Wide seats cause problems. Seating pressure drops as seat width increases. Less force is available to crush carbon particles that stick to the seats, and seats run cooler, allowing deposits to build up on them.

The seat should contact the valve face $\frac{1}{32}$ inch (0.79 mm) from the margin of the valve. When the engine reaches operating temperature, the valve expands slightly more than the seat. This moves the contact area down the valve face. Seats that make too low a contact with the valve face might lose partial contact at normal operating temperatures.

Valve seats can be reconditioned or repaired by one of two methods, depending on the seat type—machining a counterbore to install an insert seat, or grinding, cutting, or machining an integral seat.

Figure 12-69 The centerline of the guide should be concentric with the seat.

Figure 12-70 Checking valve seat width.

Cracked, heavily burnt, and loose seats should be replaced. If the seat is slightly blemished, it may only need to be refaced. Some rebuilders always replace the valve seats in an aluminum head when it is being reconditioned. This helps restore correct valve height and valve train geometry. Also, many engines have powdered metal seats. These become harder through use and can be very difficult to machine. Therefore, they are replaced with new powder metal or alloy seats.

Valve seats can be reconditioned or repaired by machining a counterbore to install an insert seat, or grinding, cutting, or machining an integral seat.

Seats should not be serviced until all other machining or repairs have been done to the head and the head has been thoroughly cleaned. This includes the reconditioning of the valve guides.

Installing Valve Seat Inserts

The following steps outline a typical procedure for valve seat insert removal and replacement.

PROCEDURE

Insert Valve Seat Removal and Replacement

- STEP 1** To remove the damaged insert, use a puller or a prybar (**Figure 12-71**).
- STEP 2** After removal, clean up the counterbore or recut it to accommodate oversized inserts.
- STEP 3** Insert the counterboring pilot into the valve guide. Then mount the base and ball shaft assembly to the gasket face angle of the cylinder head.
- STEP 4** Use an outside micrometer to accurately expand the cutterhead to a predetermined size of the counterbore (**Figure 12-72**). Remember that the counterbore should have a slightly smaller ID than the OD of the insert to provide for an interface fit.
- STEP 5** Place the valve insert counterboring tool over the pilot and ball-shaft assembly. Preset the depth of the valve seat insert at the feed screw.
- STEP 6** Cut the insert by turning the stop-collar until it reaches the present depth. Use a lubricant on the cutters for a smoother finish (**Figure 12-73**).
- STEP 7** To install the insert, heat the head in a parts cleaning oven to approximately 350°F to 400°F (176°C to 204°C). Chill the insert in a freezer or with dry ice before installation.
- STEP 8** Press the seat with the proper interference fit using a driver.
- STEP 9** When the installation is complete, the edge around the outside of the insert is staked as shown in **Figure 12-74**. By doing so, the insert will be secured more effectively in the counterbore.

Figure 12-71 Using a prybar to remove a damaged insert seal.

Figure 12-72 Using an outside micrometer to expand the cutter head to allow for an interference fit between the bore and the new valve seat.

Figure 12-73 The valve to openings of this head has been bored and is ready for new seat inserts.

Figure 12-74 Staking the valve seat to the head can be done with a sharp chisel.

Figure 12-75 The three angles of a properly finished seat.

CAUTION!

Wear the proper gloves when handling dry ice.

Reconditioning Integral Seats

The average valve seat width is 0.060 inch (1.524 mm) and begins 0.030 inch (0.7620 mm) from the valve margin. A properly reconditioned seat has three angles: top, 30 or 15 degrees; seat, 45 or 30 degrees; and throat, 60 degrees. Using three angles provides the correct seat width and sealing position on the valve face (**Figure 12-75**).

Integral valve seats can be reconditioned by grinding, cutting, or machining.

Grinding Valve Seats

When grinding a valve seat, it is very important to use the correct size pilot and grind stone. Hard seats use a soft stone and soft seats (cast iron) use a harder stone. The stone must be properly dressed and cutting oil used to aid in grinding.

SHOP TALK

Before grinding, many technicians clean the seats by placing a piece of fine emery cloth between the stone and the seat and giving the surface a hard rub. This will help prevent contamination of the seat grinding stone by any oil or carbon residue that might be present on the valve seat. Such contamination could cause glazing.

The grinding wheel is positioned and centered by inserting a properly sized pilot shaft into the valve guide (**Figure 12-76**). All valve guide service must be completed before installing the pilot.

The seat is ground by continually and quickly raising and lowering the grinder unit on and off the seat. Grinding should only continue until the seat is clean and free of defects.

Figure 12-76 Grinding the seat.

Figure 12-77 A valve seat being cut at three angles at the same time. Courtesy of Jasper Engines & Transmissions

Cutting Valve Seats

Cutting valve seats differs from grinding only in the equipment used (**Figure 12-77**). Hardened valve seat cutters replace grinding wheels. The basic seat cutting procedures are the same as those for grinding. Always check the fit of the valve face on the seat and adjust the seat as needed after initial cuts.

Checking Valve Fit

While cutting a 45-degree or other specified seat, make the seat wider than specifications. Bevel or chamfer the top of the seat with a **topping** stone (normally 30 degrees). Then bevel the bottom with a

Figure 12-78 The fit of the valve face in the seat should be checked carefully.

throating stone (normally 60 degrees). Coat the face of the valve with machinist dye, which is a Prussian blue compound. Install the valve into its seat. Then open the valve and snap it closed against the seat several times. Remove the valve and look at the pattern on the valve face and seat.

The dye should show the face making full and even contact with the seat. The contact area should also be centered on the valve seat. If the pattern on the valve face is not even, the valve should be replaced. If the pattern on the seat is not even, check the concentricity of the guide and replace the guide and/or seat.

If the contact area is above the center of the seat, it needs to be lowered (**Figure 12-78**). Cut the seat with the topping stone. This stone will also make the seat narrower. If the contact area is too low, cut the seat with the throating stone. When using the topping or throating stone or cutting bits to move the contact area, remove a little metal and recheck the contact area. Keep machining the seat until the contact area is the correct width and has the desired placement. After the contact area is acceptable, use the 45-degree stone to clean off any possible burrs caused by the cutting and grinding. Make sure all metal particles from machining the seat are totally removed before assembling the head.

Lapping Some recommend lapping the valves after the seat area has been adjusted. This procedure uses an abrasive compound to remove all small imperfections

in the contact area between the valve face and the seat. The abrasive lapping compound is spread thinly over the face of the valve. With the face against the seat, the valve is moved back and forth with a lapping tool. A lapping tool is basically a stick with a suction cup on the end. The suction cup is placed on the outside of the valve head and the stick is rotated back and forth by hand. After several rotations, the valve is removed and its face and seat are wiped clean.

VALVE STEM SEALS

Valve stem seals are used to control the amount of oil allowed between the valve stem and the guide. The stems and guides will scuff and wear excessively if they do not have enough lubrication. Too much oil produces heavy deposits that build up on the intake valve and hard deposits on the head end of the exhaust valve stem. Worn valve stem seals can increase the oil consumption by as much as 70%.

There are basically three types of seals. **Positive seals** fit tightly around the top of the guide and scrape oil off the valve stem as it moves up and down. Deflector, splash, or **umbrella-type seals** ride up and down on the valve stems to deflect oil away from the guides. O-ring seals are used to prevent oil from moving into the guide when the valve is open.

Installing Positive Valve Seals

To install a positive valve seal (**Figure 12-79**), place the plastic sleeve in the kit over the end of the valve

Figure 12-79 Installation of a positive oil seal onto a valve guide.

Figure 12-80 Valve assembly with an umbrella-type oil seal. *Courtesy of Federal-Mogul Corporation*

stem to protect the seal as it slides over the keeper grooves. Lightly lubricate the sleeve. Carefully place the seal on the cap over the valve stem and push the seal down until it touches the top of the valve guide. At this point, the installation cap can be removed and placed on the next valve. A special installation tool can be used to finish pushing the seal over the guide until the seal is flush with the top of the guide.

Installing Umbrella-Type Valve Seals

An umbrella-type seal is installed on the valve stem before the spring is installed. It is pushed down on the valve stem until it touches the valve guide boss (**Figure 12-80**). It will be positioned correctly when the valve first opens.

Installing O-Rings

When installing O-rings, use engine oil to lightly lubricate the O-ring. Then install it in the lower groove of the lock section of the valve stem (**Figure 12-81**). Make sure the O-ring is not twisted.

ASSEMBLING THE CYLINDER HEAD

Before a cylinder head is reassembled and installed, two critical measurements must be carefully checked: the installed stem height and the installed spring height.

Installed stem height is the distance between the spring seat and stem tip. A number of tools can be used to obtain an accurate stem height reading,

Figure 12-81 Valve assembly with an O-ring valve seal. *Courtesy of Federal-Mogul Corporation*

including a depth micrometer, vernier caliper, and telescoping gauge.

USING SERVICE INFORMATION

Stem height specifications are often unavailable in service manuals. As a guide for assembly, record the stem heights for all valves during disassembly.

Another specification related to installed stem height is installed spring height. Installed spring height is measured from the spring seat to the underside of the retainer when it is assembled with keepers and held in place. This measurement can be made by using a set of dividers or scales, telescoping gauge, or spring height gauge.

If the spec for installed spring height for an exhaust valve is 1.600 inches (40.64 mm), and the measurement is 1.677 inches (42.54 mm), the increase in height is 0.077 inch (1.95 mm). This means the installed stem height has also been increased by 0.077 inch (1.95 mm).

Adjustments to valve spring height can be made with valve spring inserts, otherwise known as spring shims. Even though valve shims come in only three standard thicknesses—0.060, 0.030, and 0.015 inch (1.52, .7620, and .3810 mm)—using combinations of different shims gives the correct amount of compensation (within 0.005 or 0.010 inch [0.1270 or 0.2540 mm]).

SHOP TALK

Valve keepers should be replaced in pairs. If a new keeper is mated with a used one, the spring retainer may cock and break off the valve tip or allow the assembly to come apart.

By comparing spring height to specifications, the desired amount of spring tension correction can be easily determined. For example, if spring height is 0.180 inch (4.59 mm) and the specifications call for 0.149 inch (3.78 mm), a 0.030-inch shim (0.149 inch + 0.030 inch = 0.179 inch [3.78 mm + 0.7620 mm = 4.54 mm]) would be needed. If more than one shim is required, place the thickest one next to the spring. If one side of the shim is serrated or dimpled, place that side onto the spring seat.

The end of the spring that is wound the tightest should always be placed toward the head of the valve. This is also true of mechanical surge and vibration dampers.

With the valve inserted into its guide, position the valve spring inserts, valve spring, and retainer over the valve stem. Using a valve spring compressor, compress the spring just enough to install the valve keepers into their grooves. Excess pressure may cause the retainer to damage the oil seal. Release the spring compressor and tap the valve stem with a rubber mallet to seat the keepers. When doing this, the valve will open slightly. To prevent damage to the valves, never tap on the stems with the cylinder head lying flat on the bench. Turn the head on its side or raise it off the bench.

CAUTION!

If the keepers are not fully seated, the spring assembly could fly apart and cause personal injury (or serious damage to the engine if it occurs while the engine is running). For these reasons, it is good practice to assemble the valves with the retainers facing a wall and to wear eye protection.

OHC Engines

After the valves are installed and the cylinder head is assembled, the camshaft can be installed in the cylinder head. Some engines have a separate camshaft housing that bolts to the cylinder head. This should be installed with the proper seals and gaskets. Make sure the seals are properly seated in their grooves before tightening the housing to the head.

CASE STUDY

While traveling, the engine in a family's late-model car overheats. Water is added to the radiator. Then the car is taken to a service station to be diagnosed and repaired. Simple tests reveal that a heater hose has split and is leaking coolant. The hose is replaced and new coolant added to the system. With the car repaired, the family continues on their trip.

After driving only a short time, smoke is noticed coming out of the tailpipe. The engine shakes violently whenever it is placed in a load condition. The driver turns the car around and heads back to the shop that fixed the leak. Upon arrival, the driver says the technician must have knocked something loose or broken something while replacing the hose. The technician doubts this but agrees to take another look.

A cylinder power balance test would verify this, but it cannot be conducted because of the erratic idle. Instead, the spark plugs are removed and inspected. All look normal except for plug #2, which looks newer than the rest. A compression test is taken and cylinder #2 has very low dry and wet readings. Then a cylinder leakage test is conducted. Cylinder #2 has excessive leakage and air can be felt leaving the exhaust pipe.

These test results lead to the conclusion that the engine is running on one less cylinder because an exhaust valve is not sealing. The customer still feels the technician did something wrong but agrees to allow the technician to remove the cylinder head for further diagnosis. As soon as the head is off the block, the problem is identified. The exhaust valve seat for cylinder #2 came loose from the head and is preventing the valve from closing. The technician then explains that this undoubtedly happened when the engine overheated, due to the expansion of the metal. The customer is satisfied with the explanation and allows the technician to correct the problem. The family is then able to continue their trip.

Figure 12-82 OHC camshaft bearing clearances can be checked with Plastigage.

Service to the camshaft bearings can now be done. Full-round insert bearings are pressed into the bores in the cylinder head. Special tools are designed to make this job easier. Never use a standard camshaft bearing driver and hammer to install these bearings. The hammering can easily break or damage the bearing supports. After each bearing is fully seated in its bore, double-check the alignment of the bearing's oil hole with the oil hole in the head.

Some OHCs do not have bearing inserts. The bores in the aluminum casting serve as a bearing surface. These surfaces can be cleaned up and/or align bored if needed.

Most late-model OHC engines use split bearings and bearing caps or have a separate housing for the camshaft. Working with split camshaft bearings is like working with crankshaft main bearings. This includes checking bearing clearances with Plastigage (**Figure 12-82**).

Before installing the camshaft(s), install the timing gear. Make sure the alignment pin or key is aligned. Tighten the gear-to-shaft bolt to specifications. If the head has two camshafts, the manufacturer will give specific instructions for the alignment of the timing gears and chain. Normally one camshaft is installed with the chain wrapped around its gear. Once the camshaft shaft and gear are aligned with the timing reference marks, the bearing caps are installed and tightened in a specified order and torque. Then the other camshaft is installed by slipping the gear into the chain and then setting it into the bearing journals. After the timing marks are aligned on both shafts, the bearing caps for the second camshaft are tightened. When both camshafts are in place, the chain tensioner is installed.

Figure 12-83 Coating the camshaft with lubricant. Courtesy of Dana Corporation

Prior to installation, wipe off each cam bearing with a lint-free cloth, then thoroughly coat the camshaft lobes and bearing journals with the lube recommended by the manufacturer (**Figure 12-83**).

Install the camshaft. Install new O-rings and gaskets, as required, while installing the camshaft. Some camshafts have an end thrust plate or shims to limit shaft end play. Make sure the originals are installed. After the camshaft is in place, check the end play and change the thickness of the shims as needed.

If the assembly has bearing caps, place them in their correct positions and tighten them according to specifications. Once tightened, the shaft should be able to rotate smoothly. On some engines, turning the camshaft causes the valves to open and close. If this is the case, stand the cylinder head on its end to prevent the valves from hitting the bench while you turn the camshaft. If the cam does not turn, binding might be the cause. Binding is the result of a damaged bearing, a nick on the cam's journal, or a slight misalignment of the block journals. The problem should be identified and corrected.

Gather the rocker arms, lash adjusters, pushrods, lifters, and other parts that transfer the motion of the camshaft to the valve stem. Coat all of these parts with clean engine oil. These parts should be installed according to the order given in the service manual. Some are installed before the camshaft is installed; others are installed after. Make sure all parts fit securely.

Normally the rocker arm assemblies are installed by turning the cam until the lobe for that valve faces away from a valve stem. The rocker arms can be slipped into position by depressing the valve spring slightly. Make sure the rocker arm mounting bolts are tightened to specifications. Follow the same procedure for all of the valves. The manufacturer may

recommend lubricating some of the bolts, so check the manual.

Mount all manifolds and other parts that were on the head when it was removed from the block. Use new gaskets or the correct sealant where necessary. Adjust the valve lash (clearance) and mount the head onto the block.

KEY TERMS

Broaching	Quenching
CC-ing	Reaming
Cross-flow ports	Shrouding
Damper spring	Siamese ports
Guide plate	Stainless steel
Hemi-head	Stellite
Hemispherical combustion chamber	Throating
Knurling	Topping
Margin	Tungsten inert gas (TIG)
Milling	Turbulence
Pentroof	Umbrella-type seal
Phaser	Valve face
Poppet	Valve guide
Porosity	Valve keeper
Positive seal	Valve stem
Pumping loss	Wedge-type combustion chamber
Quench area	

SUMMARY

- Pushrods are the connecting link between the rocker arm and the valve lifter.
- The rocker arm converts the upward movement of the valve lifter into a downward motion to open the valve.
- Aluminum cylinder heads are used on late-model engines because of their light weight. The thermal expansion characteristics of aluminum can lead to problems such as leaking and cracking.
- Every cylinder of a four-stroke engine contains at least one intake valve and one exhaust valve.
- Multivalve engines feature either three, four, or five valves per cylinder, which means better combustion and reduced misfire and detonation. These benefits are offset to some extent by a more complicated camshaft arrangement.
- The means of resurfacing the deck of a cylinder head include grinding, milling, belt surfacing, and broaching.

- The amount of stock removed from the cylinder head gasket surface must be limited. Excessive surfacing can create problems with the engine's compression ratio, not to mention piston/valve interference and misalignment.
- The two surfaces of a valve reconditioned by grinding are the face and the tip. Valves can be refaced on grinding or cutting machines.
- One of the fastest ways for restoring the inside diameter of a worn valve guide is knurling. Reaming increases the guide bore to take an oversize valve stem or restores the guide to its original dimension after knurling or installing inserts.
- Pressing out an old valve guide to install a new one can be difficult on some aluminum heads where the interference fit is considerable.
- To ensure proper seating of a valve, the seat must be the correct width, in the correct location on the valve face, and concentric with the guide.
- When grinding a valve seat, choosing the correct size pilot and stone is important.
- Valve stem seals are used to control the amount of oil between the valve stem and guide. Too much oil produces deposits, while insufficient lubrication leads to excessive wear.
- The valve spring closes the valve and maintains valve train contact during the opening and closing of the valve. To determine if a spring needs to be replaced, three tests are valuable: freestanding height, spring squareness, and open/close spring pressure.
- Two critical measurements that must be made before a cylinder head is reassembled are installed stem height and installed spring height. The first of these is determined by measuring the distance between the spring seat and the stem tip. The latter is measured by the spring seat to the underside of the retainer when it is assembled with keepers and held in place.

REVIEW QUESTIONS

1. What happens when spring tension is too low?
2. Define valve margin.
3. What usually causes warpage in an aluminum cylinder head?
4. What are the two ways pushrods can be checked for straightness?

5. What welding method is preferred for repairing aluminum heads?
6. Why do some technicians not consider knurling a long-term repair?
7. Which of the following is not true of knurling?
 - a. It is one of the fastest techniques for restoring the ID dimensions of a worn valve guide.
 - b. It reduces the amount of work necessary to reseat the valve.
 - c. It is useful for restoring badly worn guides to their original condition.
 - d. None of the above.
8. How does resurfacing the cylinder head of an OHC engine affect valve timing and what should be done when the head needs resurfacing?
9. To ensure proper seating of the valve, the valve seat must be _____.
 - a. the correct width
 - b. in the correct location on the valve face
 - c. concentric with the guide
 - d. all of the above
10. When grinding valve seats, _____.
 - a. a pilot shaft is inserted into the valve guide
 - b. a hard stone should be used on a hard seat
 - c. a soft stone should be used on a soft seat
 - d. all of the above
11. If the valve face and valve seat do not contact each other evenly after reconditioning, _____.
 - a. regrind with the same stone
 - b. regrind with stones of different angles
 - c. discard the cylinder head
 - d. none of the above
12. Many engines with VVT have a phaser mounted to the end of one or more camshafts. Which of the following statements is not true?
 - a. A phaser is used to alter valve timing.
 - b. Most phasers are controlled by oil pressure.
 - c. Phasers are used to change valve lift.
 - d. Phasers can be used to change valve overlap.
13. Multiple valve engines tend to be more efficient than two-valve-per-cylinder engines because they _____.
 - a. allow for increased port areas
 - b. have smaller valves
 - c. provide less restriction to the airflow
 - d. all of the above
14. Which type of surfacing machine uses underside rotary cutters?
 - a. milling
 - b. broaching
 - c. belt
 - d. grinding
15. Which of the following statements is not true?
 - a. Normally the desired valve face-to-seat contact area for intake valves is $\frac{1}{16}$ inch.
 - b. Normally the desired valve face-to-seat contact area for exhaust valves is $\frac{1}{16}$ inch.
 - c. The average valve seat width is 0.060 inch and the average seat begins 0.030 inch from the valve margin.
 - d. A properly reconditioned seat has the correct seat width and sealing position on the valve face.

ASE-STYLE REVIEW QUESTIONS

1. While discussing the reasons for resurfacing a cylinder head: Technician A says that it should be resurfaced to make it flat and very smooth so the head gasket can seal properly during engine assembly. Technician B says that it can be resurfaced to raise the compression. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
2. Technician A says that bronze valve guides retain oil better than cast-iron ones. Technician B says that cast-iron valve guides are easier to machine than bronze guides. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
3. Technician A says that positive valve stem seals fit tightly around the top of the stem. Technician B says that positive stem seals scrape oil off the valve as it moves up and down. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
4. When fitting a freshly ground valve into a freshly ground seat: Technician A says that the seat should be ground more with the same stone if the margin is too small. Technician B says that the seat should be ground more with the same stone if the valve seat is too high. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B

5. Technician A says that low spring pressure may allow a valve to float. Technician B says that excessive spring tension may cause premature valve train wear. Who is correct?
- a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
6. Technician A says that it is not necessary to measure valve stem height unless the valves have been replaced. Technician B says that the valve stem height can be adjusted with shims. Who is correct?
- a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
7. Technician A uses a 30-degree stone for topping a 45-degree valve seat. Technician B uses a 60-degree stone to lower a 45-degree valve seat. Who is correct?
- a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
8. While discussing the Valvetronic system: Technician A says that the system has no need for a throttle plate. Technician B says that the system alters the duration and the lift of the intake valves. Who is correct?
- a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
9. While checking a hydraulic phaser after the camshaft has been removed from the engine: Technician A attempts to rotate the phaser's timing gear by hand and replaces it if it does move. Technician B applies air pressure to the advance and retard ports and replaces it if the gear does not move. Who is correct?
- a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
10. While servicing a warped aluminum cylinder head: Technician A checks the thickness of the head and the specifications to be sure that material can be safely removed from the surface. Technician B replaces the head if the warpage exceeds the specified allowable amount. Who is correct?
- a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B

ENGINE SEALING AND REASSEMBLY

OBJECTIVES

- Explain the purpose of the various gaskets used to seal an engine.
- Identify the major gasket types and their uses.
- Explain general gasket installation procedures.
- Describe the methods used to seal the timing cover and rear main bearing.
- Reassemble an engine including core plugs, bearings, crankshaft, camshaft, pistons, connecting rods, timing components, cylinder head, valve train components, oil pump, oil pan, and timing covers.
- Explain the ways to prelubricate a rebuilt engine.
- Reinstall an engine and observe the correct starting and break-in procedures.

Proper sealing of an engine keeps the low-pressure liquids in the cooling system away from the cylinders and lubricating oil. It also keeps the high pressure of combustion in the cylinders. It prevents both internal and external oil leaks and suppresses and muffles noise.

TORQUE PRINCIPLES

All metals are elastic. **Elasticity** means a bolt can be stretched and compressed up to a certain point. This elastic, springlike property is what provides the clamping force when a bolt is threaded into a tapped hole or when a nut is tightened. As the bolt is stretched a few thousandths of an inch, clamping force or holding power is created due to the bolt's natural tendency to return to its original length (**Figure 13-1**).

Like a spring, the more a bolt is stretched, the tighter it becomes. However, a bolt can be stretched too far. This is obvious when the grip on the wrench feels “mushy.” At this point, the bolt can no longer safely carry the load it was designed to support, called the modulus of elasticity.

If a bolt is stretched into **yield**, it takes a permanent set and never returns to normal (**Figure 13-2**). The bolt will continue to stretch more each time it is used, just like a piece of taffy that is stretched until it breaks. Proper use of torque will avoid this yield condition.

Figure 13-1 Clamping force results from bolt stretch.
Courtesy of Federal-Mogul Corporation

Figure 13-2 These bolts have been torqued beyond their yield. Note the soda bottle effect.

TABLE 13-1 THE EFFECT OF LUBRICATION ON BOLT TORQUE SPECIFICATIONS

Bolt Size	Thread	Lube	Torque	Change
$\frac{5}{16}$ -18	COARSE	None	29 ft.-lb	—
	COARSE	Plated and cleaned	19 ft.-lb	-34%
	COARSE	SAE 20 oil	18 ft.-lb	-38%
	COARSE	SAE 40 oil	17 ft.-lb	-41%
	COARSE	SAE 30 oil + plating	16 ft.-lb	-45%
	COARSE	Lithium grease	16 ft.-lb	-45%
	COARSE	Dry moly film	14 ft.-lb	-52%
	COARSE	Graphite and oil	13 ft.-lb	-55%
$\frac{1}{2}$ -13	COARSE	None	121 ft.-lb	—
	COARSE	Plated and cleaned	90 ft.-lb	-26%
	COARSE	SAE 20 oil	87 ft.-lb	-28%
	COARSE	SAE 40 oil	83 ft.-lb	-31%
	COARSE	SAE 30 oil + plating	79 ft.-lb	-35%
	COARSE	Lithium grease	79 ft.-lb	-35%
	COARSE	Dry moly film	66 ft.-lb	-45%
	COARSE	Graphite and oil	62 ft.-lb	-49%

*Use these lubrication percentages to decrease the torque specifications for other bolt sizes.

Appendix B gives standard bolt and nut torque specifications. If the manufacturer's torque specifications are available, follow them precisely.

Nonplated bolts have a rougher surface than plated finishes. Therefore, it takes more torque to produce the same clamping force as on a plated bolt.

Most printed torque values are for dry, plated bolts. Lubricants are beneficial when working with engines. They provide smoother surfaces and more consistent and evenly loaded connections. They also help reduce thread galling.

Reusing a dry nut will produce a connection with decreasing clamp force each time it is used. Nut threads are designed to collapse slightly to carry the bolt load. If dry nuts are reused, increased thread galling will result each time the nuts are reused at the same torque.

Lubrication of fasteners is recommended for consistency (**Table 13-1**). However, be sure to lubricate all the bolts with the same lubricant. Some lubricants are more slippery than others, which affects torque values. Lubricate the bolt, never the hole. Otherwise, the bolt may merely be tightening against the oil in the hole.

If a bolt with a reduced shank diameter (for example, a connecting rod bolt) is specified by the OEM,

never replace it with a standard, straight shank bolt. A reduced shank diameter bolt looks “dog-boned.” Its function is to reduce the stress on the threads by transferring it to the shank. A standard bolt under similar conditions would break very quickly at the threads.

Keep the following points in mind:

1. Visually inspect the bolts.

- Threads must be clean and undamaged. Discard all bolts that are not acceptable.
- Use liquid sealant or engine oil on the threads and seating face of cylinder head bolts to prevent seizure from rust and corrosion. This is particularly important for an aluminum block or head. Use sealant on those bolts that hold in coolant or oil.
- Install bolts in their proper holes.
- Run a nut over the bolt's threads by hand. Discard it if any binding occurs.
- Clean bolt and cylinder block threads with a thread chaser or tap (**Figure 13-3**).

2. Apply a light coat of 10W engine oil to the threads and bottom face of the bolt head. A sealer is required for a bolt that enters a water jacket.

Figure 13-3 Cleaning bolt holes with tap. *Used with permission of Detroit Gaskets*

This will stop seepage around the bolt threads. Seeping coolant could get in the oil or cause corrosion that might damage parts, resulting in engine failure.

3. Tighten bolts in the recommended sequence. This is important to prevent warpage of the parts.
 - Use an accurate torque wrench.
 - Tighten bolts according to the recommended steps.
4. If bolt heads are not tight against the surface, the bolts should be removed and washers installed.
5. Make sure the bolt is the proper length (not too long).

Bolt hole threads often pull up, leaving a raised edge around the hole (**Figure 13-4**). If a part has been resurfaced, the threads might run up to the surface. In either case, the bolt holes should be tapered at the surface by chamfering and the threads cleaned with an appropriate size bottoming tap. Always repair damaged threads.

Chapter 4 for common procedures on thread repair.

Figure 13-4 Bolt hole threads can pull up, leaving a raised edge. Also, if the block has been resurfaced, the threads may run up to the surface. In either case, the hole must be chamfered.

SHOP TALK

Impact wrenches should only be used to loosen nuts and bolts. Use other power or hand tools to tighten them. Final tightening should always be done with a torque wrench.

Thread Repair

A common fastening problem is threads stripping inside an engine block, cylinder head, or other structure. This problem is usually caused by overtightening or by incorrectly threading the bolt into the hole. Rather than replacing the block or cylinder head, the threads can be replaced by the use of threaded inserts. The helically coiled insert is the most commonly used.

Chapter 4 for the procedures for reconditioning fastener threads.

Torque-to-Yield (TTY) Bolts

Some fasteners are intentionally torqued into a yield condition. These fasteners, known as **torque-to-yield (TTY)** bolts, are designed to stretch when properly tightened. When a bolt is stretched to its yield point, it exerts its maximum clamping force. TTY bolts are not ordinary bolts. The bolt shank is designed to stretch (**Figure 13-5**) and spring back up to its yield point when tightened. Once at the yield point, the bolt becomes permanently stretched and will not return to its original length. Therefore, TTY bolts should not be reused.

TTY bolts are commonly used as cylinder head bolts but may be used in other applications. Service

Figure 13-5 TTY bolts are designed with a reduced shank diameter; this is where the intended stretch occurs.

Figure 13-6 TTY bolts are tightened to a specified torque and then turned to an additional number of degrees.

manuals note the location of TTY bolts and give the proper tightening sequence for them.

Tightening a TTY bolt involves two distinct steps: Tighten the bolt to the specified torque, and then turn the bolt to a specified angle (measured in degrees) to load the bolt beyond its yield point (**Figure 13-6**). A torque angle gauge is required to do this. This gauge fits between the drive of the torque wrench and the socket. Once the specified torque is reached, the angle gauge is set to zero. Then the bolt is turned until the specified angle is read on the gauge.

GASKETS

When parts are bolted together, it is nearly impossible to obtain a positive seal between the parts. **Gaskets** are used to provide that seal. Some gaskets seal low-pressure fluids, such as oil and coolant, while others also seal high-combustion pressures, such as head gaskets. Gaskets also serve as spacers, wear insulators, and vibration dampers. Gaskets are only used between two stationary parts. Seals are used if one of the parts moves.

Gaskets can be made of paper, fiber, steel, cork, synthetic rubber, and combinations of these materials. Most late-model engines have molded silicone rubber gaskets and cut plastic gaskets with silicone sealing beads. The gaskets may incorporate flexible graphite cores, specialized surface coatings, asbestos-free materials, elastomeric beading, reinforced cork products, wire-ring combustion seals, flat-plate hoop-strength constructions, and many other design variations (**Figure 13-7**). The goal of all designs is provide long-term leak-free joints.

Cut Gaskets

Gaskets made of paper, fiber, and cork are normally called soft, cut gaskets (**Figure 13-8**). Each gasket is

cut to the desired size and shape from a sheet of material.

Paper/Fiber Gaskets These are made of a fiber-reinforced paperlike material. This treated paper seals low-pressure, low-temperature areas well. For some applications, paper gaskets may be relatively thick. Paper gaskets are commonly used between the different housings and covers in a transmission or for some water pumps. These gaskets seldom need an additional sealant; however, a thin coating of adhesive may be used to hold the gasket in place while it is installed.

Cork Gaskets Cork gaskets are used to seal low-pressure areas like valve covers and oil pans. In most cases, cork gaskets are not used on today's engines. In fact, most gasket manufacturers substitute a rubber gasket for the original cork. Cork gaskets are very soft, easily distorted, and absorbent. In fact, they will weep some of the fluid they are sealing. They also tend to become brittle and crack over time. Composite gaskets, typically rubberized cork, are often used (**Figure 13-9**). These have a longer service life. A sealant or adhesive is often used to ease installation and to improve their effectiveness.

Molded Rubber Gaskets

Molded rubber gaskets provide excellent sealing and are commonly used on today's engines. These gaskets are made by injecting synthetic rubber (neoprene, nitrile, silicone, or other similar material) into a mold to form one-piece gaskets. Molded gaskets retain their flexibility and are durable. Molded gaskets are often used to seal intake manifolds, some thermostat or water pump housings, valve covers, and oil pans.

Some molded gaskets have a steel insert that adds stiffness and strength to the gasket (**Figure 13-10**). Some gaskets may also have reinforcements around the bolt holes (**Figure 13-11**) to limit the amount of crush when the parts are tightened together.

WARNING!

Do not use sealant or adhesive on rubber gaskets; they can prevent the gasket from sealing.

Manufacturers may not use premade gaskets when they are making their engines. Rather they use chemical gasketing. Robotic equipment applies a

Figure 13-7 Typical engine gasket and seal locations.

bead of sealant around the sealing area. The result is called a “formed-in-place” gasket.

Hard Gaskets

Hard gaskets are made from steel, stainless steel, copper, or a combination of metals and other materials. Often the metal is enclosed by a compressible and heat-resistant clay/fiber or Teflon® compound (Figure 13-12). Hard gaskets are typically for

Figure 13-12 Composition of a Teflon®-coated perforated steel core gasket used mainly as head and intake manifold gaskets. *Courtesy of Dana Corporation*

Figure 13-13 A full gasket set contains the gaskets and seals required for rebuilding an engine.

cylinder heads, exhaust manifolds, EGR valves, and some intake manifolds.

Replacement Gaskets

Gaskets can be purchased individually or in sets. Sets are often available for the service being performed on the engine. The most common are timing cover, head, manifold, oil pan, and full sets. A full set contains all gaskets and seals required for rebuilding an engine (Figure 13-13). Normally there are more gaskets in a set than are needed. A particular engine may have been available with different equipment and the extra gaskets are for those variations. All gaskets need to be properly installed to provide a good, durable seal.

SHOP TALK

Before replacing a faulty gasket, check for any TSBs on the engine. There may be a recommended replacement for the OEM gasket. For example, some GM engines built between 1996 and 2002 have experienced premature intake manifold gasket failures. These failures are normally caused by the corrosive effects of organic acid technology (OAT) coolant. The cure is a replacement gasket that is less susceptible to OAT.

General Gasket Installation Procedures

The following instructions will serve as a helpful guide for installing gaskets. Because there are many different gasket materials and designs, it is impossible to list directions for every type of installation. Always follow

any special directions provided in the instructions packed with most gasket sets.

1. Never reuse old gaskets. Even if the old gasket appears to be in good condition, it will never seal as well as a new one.
2. Handle new gaskets carefully. Be careful not to damage the new gaskets before placing them on the engine.

USING SERVICE INFORMATION

Always refer to the specific engine and engine part section of the service manual for the recommended procedures for using sealants.

SHOP TALK

Some technicians tend to use too much sealant on gaskets. Do not make this mistake. Because sealants have less strength than gasket materials, they create weaker joints. They can also prevent some gasket material from doing what it is supposed to do, which is to soak up oil and swell to make a tight seal.

3. Cleanliness is essential. New gaskets seal best when used on clean surfaces. Thoroughly clean all mating surfaces of dirt, oil deposits, rust, old sealer, and gasket material.
4. Use the right gasket in the right position. Always compare the new gasket to the mating surfaces to make sure it is the right gasket. Check that all bolt holes, dowel holes, coolant, and lubrication passages line up perfectly with the gasket. Some gaskets have directions such as “top,” “front,” or “this side up” stamped on one surface (Figure 13-14).

Figure 13-14 Some gaskets have installation directions stamped on them. *Courtesy of Detroit Gaskets*

An upside-down or reversed gasket can easily cause a loss of oil pressure, overheating, and engine failure.

5. Use sealants and adhesives only when the engine or gasket manufacturer recommends their use. Some chemicals will react negatively with the gasket's coating. Normally if a gasket requires a sealant, it will be included with the gasket.
6. Make sure the threads of all fasteners are clean and undamaged.

SPECIFIC ENGINE GASKETS

There is a wide variety of gaskets used on engines, each with its own purpose, and each is designed for that application. The following is a discussion of the most common ones.

Cylinder Head Gaskets

Cylinder head gaskets seal the gap between the cylinder head and the block (Figure 13-15). The head gasket has a very demanding job. It must seal the combustion chambers and the coolant and oil passages between the head and the block. The oil and coolant are low-temperature and low-pressure fluids. The gasket must prevent leakage inside and outside the engine. It must be able to do this while sustaining wide temperature ranges and pressures inside each cylinder. When a cold engine is first started, parts near the combustion chamber are very cold. Then, after only a few minutes of running, these same parts might reach 400°F (204°C). The inner edges of the head gasket are exposed to combustion temperatures from 2,000°F to 4,000°F (1,093°C to 2,204°C). Pressures in the combustion chamber also vary tremendously. On

Figure 13-15 Different designs of cylinder head gaskets and replacement head bolts. *Courtesy of Detroit Gaskets*

the intake stroke a vacuum or negative pressure is present. After combustion, pressure peaks of approximately 1,000 psi (6,895 kPa) occur. This extreme change from low to high pressure happens in a fraction of a second.

Cylinder head gaskets must simultaneously do the following:

- Seal intake stroke vacuum, combustion pressure, and the heat of combustion.
- Prevent coolant leakage and resist rust, corrosion, and, in many cases, meter coolant flow.
- Seal oil passages through the block and head while resisting chemical action.
- Allow for lateral and vertical head movement as the engine heats and cools.
- Be flexible enough to seal minor surface warpage while being stiff enough to maintain adequate gasket compression.
- Fill small machining marks that could lead to serious gasket leakage and failure.
- Withstand forces produced by engine vibration.

Head gaskets for many late-model cast-iron engines have raised silicone, **Viton**, or fluoroelastomer sealing beads on their face to increase the clamping pressure around troublesome areas. Most head gaskets have a steel fire ring that surrounds the top of the cylinder. These protect the material used elsewhere in the gasket. The durability of a head gasket can also be improved by using strong, high-temperature fibers such as aramid and kevlar and by adding reinforcements around oil passages.

Bimetal Engine Requirements Most late-model engines have aluminum cylinder heads and cast-iron blocks. When heated, aluminum expands two to three times more than steel. This creates a back-and-forth scrubbing action on a head gasket as the engine temperature changes (**Figure 13-16**). This movement can tear a gasket apart if it is not designed to handle it. To reduce the chances of a gasket tearing, graphite or specially coated gaskets are used. **Graphite** is a relatively soft material that can withstand high temperatures. It is a natural lubricant, so graphite-faced gaskets are not coated. Teflon, molybdenum, and other similar slippery nonstick coatings are used on other gasket designs to prevent the gasket from sticking to either surface. This allows the head to expand and contract without destroying the gasket.

Multilayer Steel (MLS) Many engines have **multilayer steel (MLS)** head gaskets. These gaskets are

Figure 13-16 Thermal growth characteristics of bimetal engines.

comprised of three to seven layers of steel. The outer layers are normally embossed stainless spring steel coated with a thin layer of an antifriction coating of Teflon, nitrile rubber, or Viton (**Figure 13-17**). The inner layers provide the necessary thickness. The use of an MLS gasket reduces the load on the head bolts and allows them to retain their shape after they are tightened in place. They are also very durable. MLS gaskets require an extremely smooth finish on the engine block and cylinder head. They are also used with TTY bolts.

SHOP TALK

One of the problems with resurfacing the head on an OHC engine is that cam timing is affected. This is caused by the fact that the camshaft is now closer to the crankshaft. Some aftermarket gasket companies offer an MLS gasket set made up of top and bottom layers and several steel spacer layers. The spacers fit in the middle of the outer layers to achieve the required thickness. These stackable head gaskets can also be used to lower compression when a turbocharger or supercharger is installed.

Head Gasket Failures When a head gasket has failed, it is important to correct the problem that caused it.

Figure 13-17 Two examples of the construction of an MLS head gasket. Courtesy of Federal-Mogul Corporation

Figure 13-18 shows the common causes of failure and the systems that should be checked.

Some engines will have hot spots that cannot be corrected. These engines typically have exhaust ports that are located next to each other. Heat builds up in these areas and causes the head to swell and crush the head gasket. Gasket manufacturers often incorporate reinforcements in those areas to resist the crushing.

SHOP TALK

It is important to find out why a head gasket has failed. When inspecting a gasket, measure its thickness at the damaged and undamaged areas. If the damaged area is thinner, the gasket failed because of overheating or a hot spot. If the fire ring around the cylinder bores is cracked or burnt, preignition or detonation caused the gasket to fail.

Problem	Probable Cause
Preignition/Detonation	Incorrect ignition timing Incorrect air-fuel mixture Vacuum leak Faulty cooling system
Overheating	Restricted radiator Cooling system leak Faulty thermostat Faulty water pump Inoperative cooling fan Faulty EGR system
Improper Installation	Wrong surface finish Incorrect bolt-tightening sequence Use of stretched or damaged bolts Improper use of sealant Use of incorrect gasket Dirty mating surfaces
Hot Spots	Use of incorrect gasket

Figure 13-18 Leading causes of cylinder head gasket failure.

Head Bolts Installation failures are commonly caused by head bolt problems. When installing a cylinder head and bolts, follow these guidelines:

- Make sure all head bolts are clean and have undamaged threads. Replace any bolts that are nicked, deformed, or worn.
- Make sure the correct length bolt is installed in the bore. Some engines use longer bolts in some locations.
- Check the length of each bolt and compare the measurements. Longer than normal bolts are stretched and should not be reused.
- Inspect the shank or top of the threaded area of the bolt for evidence of stretching.
- Never reuse TTY bolts.
- When installing an aluminum head, use hardened steel washers under the bolts. Place the washers so their rounded edge faces up.
- Clean the thread bores in the engine block with a bottoming tap.
- Make sure the top of each thread bore is chamfered.
- If the head has been resurfaced, make sure the bolts do not bottom out in their bores. If they do, install hardened steel washers under the bolt heads to raise them, or use a head gasket shim to bring the head to its proper height.

Figure 13-19 Assorted intake and exhaust manifold gaskets for diverse applications. *Courtesy of Detroit Gaskets*

- Lubricate the threads and the bottom of the bolt head with engine oil.
- Apply the correct type of thread sealant to all bolts that go into a coolant passage.

Manifold Gaskets

There are three basic types of manifold gaskets—the intake manifold, exhaust manifold, and a combination intake and exhaust. Combination gaskets are often used on inline engines without cross-flow heads. Manifold gaskets are made of a variety of materials, depending on the application. Each type of manifold gasket has its own sealing characteristics and problems (**Figure 13-19**). Therefore, be sure to follow the manufacturer's instructions when installing them.

Before installing a manifold and its gasket, make sure that the mating surfaces on the head and manifold are flat and free of damage. Also, always follow the recommended bolt-tightening sequence and use the exact torque specs.

Valve Cover Gaskets

Valve cover gaskets must seal between a steel, aluminum, magnesium, or molded plastic cover and a cylinder head surface that might not be machined. On OHC engines, the valve cover may be called the cam or cylinder head cover. Cam covers are normally made of die-cast aluminum. Some cylinder cover gaskets have spark plug gaskets integrated into the gasket (**Figure 13-20**). When installing these, make sure the gasket is perfectly aligned. Valve cover bolts are usually widely spaced so the gasket material must be able to seal without being tightly clamped. Valve cover gaskets must be able to withstand high temperatures and the caustic action of acids in the oil.

On older engines, the most commonly used material is a blend of cork and rubber particles. Late-model

Figure 13-20 A cylinder cover gasket with integrated spark plug gaskets. *Courtesy of Toyota Motor Sales, U.S.A., Inc.*

engines normally have gaskets made of synthetic rubber. Whether it is a cork/rubber or synthetic rubber gasket, it must be a perfect fit.

Oil Pan Gaskets

An oil pan gasket seals the joint between the oil pan and the bottom of the block (**Figure 13-21**). The gasket might also seal the bottom of the timing cover and the lower section of the rear main bearing cap.

Figure 13-21 Oil pan gasket installation; note the points where a liquid gasket is required.

Like valve cover gaskets, the oil pan gasket must resist hot, thin engine oil. Oil pans are usually made of stamped steel, cast iron, or cast aluminum. Because of the added weight and splash of crankcase oil, the pan has many assembly bolts closely spaced. As a result, the clamping force on the oil pan gasket is great.

Oil pan gaskets are made of several types of material. A commonly used material is synthetic rubber, known for its long-term sealing ability. It is tough, durable, and resists hot engine oil. Synthetic rubber gaskets are easy to remove, so the sealing surfaces need less cleanup.

Many late-model engines use a hard gasket with a bead of sealant around the inside dimensions of the gasket (**Figure 13-22**). The bead increases clamping pressures and provides a positive seal.

The oil pan on some engines is comprised of two parts: the upper unit, which is made of aluminum or magnesium, and the lower unit, which is made of stamped steel (**Figure 13-23**). A gasket is used to seal

Figure 13-22 A hard oil pan gasket with a sealant bead.

Figure 13-23 A two-piece oil pan assembly with a baffle plate.

Figure 13-24 Typical EGR valve gaskets. Courtesy of Federal-Mogul Corporation

the two units. Many engines also have a baffle assembly that must be bolted to the crankcase before the oil pan is installed.

Carefully follow the recommendations of the OEM and gasket manufacturer. Before installing a stamped steel oil pan, make sure its flange is flat. Tighten the oil pan bolts according to specifications and in the sequence given in the service manual.

EGR Valve

The exhaust gas recirculation (EGR) valve takes a sample of the exhaust gases and introduces it back into the cylinders. This reduces combustion temperatures and prevents NO_x from forming. The sealing surface of the valve should be carefully inspected. Use a file to remove any minor imperfections that may prevent the valve from sealing. Also make sure that the new gasket is the correct size; some applications have specifically sized holes in the gasket that are used to regulate exhaust flow (**Figure 13-24**). Using the wrong gasket could change how the engine performs.

ADHESIVES, SEALANTS, AND OTHER CHEMICAL SEALING MATERIALS

A number of chemicals can be used to reduce labor and ensure a good seal. Many gasket sets include a label with the recommended chemical to use with that gasket set. Some even include sealers when the OEM used a sealer to replace a gasket and a gasket cannot be manufactured for that application. They also include sealers when gasket unions need a sealant to ensure a good seal.

SHOP TALK

Chemical adhesives and sealants give added holding power and sealing ability where two parts are joined. Sealants usually are added to threads where fluid contact is frequent. Chemical thread retainers are either **aerobic** (cures in the presence of air) or **anaerobic** (cures in the absence of air). These chemical products are used in place of lock washers.

Figure 13-25 An adhesive is often used to hold a gasket in place during assembly. Courtesy of Federal-Mogul Corporation

Adhesives

Gasket adhesives form a tough bond when used on clean, dry surfaces. Adhesives do not aid the sealing ability of the gasket. They are meant only to hold gaskets in place during assembly. Use small dabs. Do not assemble components until the adhesive is completely dry (**Figure 13-25**).

Sealants

Manufacturers sometimes specify the use of sealants to assist a gasket or seal or to form a new gasket. These sealants should only be used when specified by the manufacturer. Also make sure to use the specific sealant recommended by the manufacturer.

WARNING!

Never use a sealant or liquid gasket material on exhaust manifolds.

General-Purpose Sealants General-purpose sealers are liquid and available in a brush type (known as brush tack) or an aerosol type (known as spray tack). General-purpose sealers (**Figure 13-26**) form a tacky, flexible seal when applied in a thin, even coat that aids in gasket sealing by helping to position the gasket during assembly.

WARNING!

Make sure every sealant you use on today's engines is oxygen sensor safe.

Figure 13-26 Applying gasket sealer with a brush. Courtesy of Federal-Mogul Corporation

WARNING!

Never use a hard-drying sealant (such as shellac) on gaskets. It will make future disassembly extremely difficult and might damage the gasket.

Thread Sealants Bolts that pass through a liquid passage should be coated with Teflon thread (**Figure 13-27**) or a brush-on thread sealant. Some head bolts or water pump bolts tighten into a coolant passage and must be sealed or they will leak. These flexible sealants are nonhardening sealers that fill voids, preventing the fluid from running up the threads. They resist the chemical attack of lubricants, synthetic oils, detergents, antifreeze, gasoline, and diesel fuel.

Figure 13-27 Bolts that pass through a liquid passage should be coated with Teflon or similar thread sealant.

Figure 13-28 Applying a bead of RTV gasket material on a water pump. Courtesy of Loctite Corporation

Silicone Sealants **Silicone** (or formed-in-place) **gaskets** are a liquid sealant applied directly to mating surfaces and allowed to cure in place. Many technicians use silicone gasketing to aid in sealing the corners, notches, or dovetails of gaskets. **Room temperature vulcanizing (RTV)** silicone sealing products are the most commonly used formed-in-place (FIP) gasket products. RTV is an aerobic sealant, which means it cures or hardens in the presence of air. RTV can be used to seal two stationary parts such as water pumps (**Figure 13-28**) and oil pans. It cannot be used as a head or exhaust gasket or in fuel systems. It should also not be used to coat gaskets. RTV comes in a variety of colors that denote the proper application. Black is for general purpose; blue is for special applications; and red is for high-temperature requirements. Always use the correct type for the application. Also make sure that the RTV is oxygen sensor safe. RTV silicone sealants are impervious to most fluids, are extremely resistant to oil, have great flexibility, and adhere very well to most materials.

WARNING!

Be careful not to use excessive amounts of RTV. If too much is applied, it can loosen up and get into the oil system where it can block an oil passage and cause severe engine damage.

To use RTV, make sure the mating surfaces are free of dirt, grease, and oil. Apply a continuous $\frac{1}{8}$ -inch bead on one surface only (preferably the cover side). Encircle all bolt holes (**Figure 13-29**). Adjust the shape before a skin forms (in about 1 minute), then remove the excess RTV with a dry towel or paper towel. Press the parts together. Do not slide the parts

Figure 13-29 When applying RTV, make sure the bolt holes are encircled.

together—this will disturb the bead. Tighten all retaining bolts to the specified torque.

CAUTION!

The uncured rubber contained in RTV silicone gasketing irritates the eyes. If any gets in your eyes, immediately flush with clean water or eyewash. If the irritation continues, see a doctor.

Anaerobic Sealants These materials are used for thread locking as well as gasketing. They are mostly used to hold sleeves, bearings, and locking screw nuts in places subject to much vibration. Anaerobic sealers are intended to be used between the machined surfaces of rigid castings, not on flexible stampings. Use anaerobic sealants only when specified.

SHOP TALK

Once hardened, an anaerobic bond is unbelievably tenacious and can withstand high temperatures. Different anaerobic sealants are for specific purposes and not readily interchangeable. For example, thread-locking products range from medium-strength antivibration agents to high-strength, weldlike retaining compounds. The inadvertent use of the wrong product could make future disassembly impossible.

Antiseize Compounds

Antiseize compounds prevent dissimilar metals from reacting with one another and seizing. This material is used on many fasteners, especially those used with aluminum parts. Always follow the manufacturer's recommendations when using this compound.

OIL SEALS

Seals keep oil and other fluids from escaping around a rotating shaft. There are three basic oil seal designs: the fiber packing, the two-piece split lip design, and the one-piece radial design (**Figure 13-30**).

SHOP TALK

Whenever installing an oil seal, make sure its lip seal is lubricated with a light coating of grease. Also, make sure the lip portion of the seal is facing the direction that oil is coming against.

Timing Cover Oil Seals

An oil seal in the timing cover prevents oil from leaking around the crankshaft. Its installation often requires the use of a special tool (**Figure 13-31**) or a driver. It is important that the seal be positioned squarely in the bore of the cover and the crankshaft be positioned in the center of the seal.

Rear Main Bearing Seals

Rear main bearing seals keep oil from leaking around the rear main bearing. There are two basic types: wick- or rope-type packing and molded synthetic rubber.

Wick- or rope-type packings are common on many older engines. Molded synthetic rubber lip-type seals are used on many newer engines. They do a good job of sealing as long as the surface of the shaft is very smooth. Synthetic rubber seals may be retrofitted to some older engines that have wick seals.

Three types of synthetic rubber are used for rear main bearing seals. **Polyacrylate** is commonly used because it is tough and abrasion resistant, with

Figure 13-31 The installation of the timing cover oil seal requires the use of a special tool or driver. *Courtesy of Chrysler LLC*

moderate temperature resistance to 350°F (177°C). Silicone synthetic rubber has a greater temperature range, but it has less resistance to abrasion and is more fragile than polyacrylate. Silicone seals must be handled carefully during installation to avoid damage. Viton has the abrasion resistance of polyacrylate and the temperature range of silicone, but it is the most expensive of the synthetic types. Synthetic rubber seals may be one piece (**Figure 13-32**) or two pieces (**Figure 13-33**).

Always check the shaft for smoothness. Shafts should be free of nicks and burrs. Carefully remove any roughness with a very fine emery cloth and clean the shaft thoroughly. The shaft should have a highly polished appearance and a smooth feel. Also, be sure to check and clean the oil slinger and oil return channel in the bearing cap.

Figure 13-30 The three basic oil seal designs. *Courtesy of Detroit Gaskets*

Figure 13-32 Installing a one-piece rubber rear crankshaft seal.

Figure 13-33 Typical two-piece rubber rear crankshaft seal.

ENGINE REASSEMBLY

When reassembling an engine, the sequence is essentially the reverse of the teardown sequence given in a previous chapter. Always refer to the service manual before assembling an engine.

Installing the Cylinder Head and Valve train

Use a wire brush to clean the threads of the head bolts. Then check their condition and length. Many engines use head bolts of different lengths (**Figure 13-34**) and their location is given in the service manual. Lightly lubricate the threads with clean engine oil.

Position the head gasket on the block and make sure it matches the bores in the block. Place the cylinder head onto the block. Make sure that the dowel pins (**Figure 13-35**) are in place and that the head and block are properly aligned.

Tighten the head bolts according to the recommended sequence (**Figure 13-36**) and to the specified torque. Most heads are tightened in a sequence that starts in the middle and moves out to the ends. The bolts are generally tightened in two or three stages.

Before inserting the pushrods, apply some assembly lube to both ends. Liberally coat the rocker arms with assembly lube or clean engine oil. Then install the pushrods and rocker arms. Many OHV engines have positive stop rocker arm adjustments. This means that when torquing the rocker arms to spec, the plunger of the hydraulic lifter is properly positioned, giving the correct lifter adjustment.

Figure 13-34 Head bolts are different lengths in some engines. Courtesy of Ford Motor Company

Figure 13-35 When installing a cylinder head onto an engine block, make sure that the dowel pins are securely installed in the block and that the head gasket is in the correct position.

Figure 13-36 Always follow the specified tightening sequence when torquing cylinder head bolts.

Timing Belts and Chains

The alignment of the camshaft(s) with the crankshaft is critical. The alignment marks and the correct procedure for doing this vary with the engine design. Many engines have additional chains or belts for the balance shafts and oil pump. DOHC engines may have a chain that connects the two camshafts. All of these must be properly timed. Check the service

manual for the correct alignment and tension adjustment procedures (**Figure 13-37**). Make sure that the belt or chain tensioners are set properly.

USING SERVICE INFORMATION

Normally, camshaft timing marks are shown in the engine section of a service manual under the heading of Timing Belt or Chain R&R.

Timing belts can be replaced with the engine in the vehicle or when the engine is on a stand. Photo Sequence 10 shows a typical procedure for changing a timing belt with the engine in a vehicle.

After the belt is installed, adjust its tension according to the manufacturer's recommendations. Then, by turning the crankshaft, rotate the engine through two complete turns and recheck the tension. Now rotate the engine through at least more revolutions. Recheck the timing marks on the crankshaft and

Timing Chain Index Marks

Figure 13-37 Note the timing marks and position of the chain tensioners on this DOHC engine.

Replacing a Timing Belt on an OHC Engine

P10-1 Disconnect the negative cable from the battery prior to removing and replacing the timing belt.

P10-2 Carefully remove the timing cover. Be careful not to distort or damage it while pulling it up. With the cover removed, check the immediate area around the belt for wires and other obstacles. If some are found, move them out of the way.

P10-3 Align the timing marks on the camshaft's sprocket with the mark on the cylinder head. If the marks are not obvious, use a paint stick or chalk to clearly mark them.

P10-4 Carefully remove the crankshaft timing sensor and probe holder.

P10-5 Loosen the adjustment bolt on the belt tensioner pulley. It is normally not necessary to remove the tensioner assembly.

P10-6 Slide the belt off the crankshaft sprocket. Do not allow the crankshaft pulley to rotate while doing this.

Replacing a Timing Belt on an OHC Engine (*continued*)

P10-7 To remove the belt from the engine, the crankshaft pulley must be removed. Then the belt can be slipped off the crankshaft sprocket.

P10-8 After the belt has been removed, inspect it for cracks and other damage. Cracks will become more obvious if the belt is twisted slightly. Any defects in the belt indicate it must be replaced.

P10-9 To begin reassembly, place the belt around the crankshaft sprocket. Then reinstall the crankshaft pulley.

P10-10 Make sure the timing marks on the crankshaft pulley are lined up with the marks on the engine block. If they are not, carefully rock the crankshaft until the marks are lined up.

P10-11 With the timing belt fitted onto the crankshaft sprocket and the crankshaft pulley tightened in place, the crankshaft timing sensor and probe can be reinstalled.

P10-12 Align the camshaft sprocket with the timing marks on the cylinder head. Then wrap the timing belt around the camshaft sprocket and allow the belt tensioner to put a slight amount of pressure on the belt.

camshaft. If necessary, readjust the timing and tension.

Adjusting Valves

Nearly all engines must have their valve clearance set before starting after a rebuild. Engines with solid lifters also require periodic valve adjustments. Valve clearance is called **valve lash** and is checked by inserting a feeler gauge between the valve tip and the rocker arm or cam lobe. The proper amount of valve lash allows for the expansion of parts as the engine's temperature rises. This prevents excessive wear and/or damage to the valve train. It also minimizes valve train noise. Always refer to the service manual before adjusting valve lash.

Valve lash is adjusted in many different ways, depending on engine design. It is extremely important to make sure that the valves are totally closed before making an adjustment. Most OHV engines with hydraulic lifters are adjusted, one cylinder at a time, by bringing a cylinder to exact TDC. At this point the intake and exhaust valves are fully closed and the lifter is on the heel of the cam lobe. Rotate a valve's pushrod with your fingers while tightening the rocker arm's pivot nut. When the pushrod has some resistance, turn the nut an additional $\frac{1}{8}$ to $\frac{1}{2}$ turn. Once the valves of that cylinder are adjusted, the next cylinder in the firing order is brought to TDC and its valves adjusted. The process is repeated until all valves have been adjusted. Valve lash can be adjusted with the engine in or out of the vehicle.

SHOP TALK

Pay close attention to the valve lash specs. Typically the exhaust valves have a different lash spec than the intakes.

The procedure for adjusting an OHV with solid lifters is similar, except there must be a clearance between the top of the valve stem and the rocker arm tip. The lash is measured with a feeler gauge and an adjustment screw set once the desired lash is present. In most cases, a locking nut surrounds the screw. This nut is tightened while the screw is held in position so the adjustment does not change.

Similar lash adjustment procedures are used on some OHC engines. An adjustment screw at one end of the rocker arm is tightened or loosened to obtain the desired lash. To adjust the valves, make sure the valve is fully closed and loosen the adjuster locknut. Then turn the screw to achieve the proper clearance. While holding the screw and preventing it from

Figure 13-38 Some overhead cam engines feature a cam follower with an adjustment screw. *Courtesy of Ford Motor Company*

turning, tighten the locknut. Follow the same procedure for each valve that needs to be adjusted.

Some OHC engines have adjustable cam followers (**Figure 13-38**). Lash is changed by turning the adjuster.

Valve lash is controlled by select shims on many OHC engines. The shim sits between the cam lobe and the cam follower placed over the valve assembly. Valve lash is adjusted by inserting a shim of a different thickness into the follower.

PROCEDURE

Adjusting the valves on an engine that uses shims for valve clearance.

1. Rotate the crankshaft until piston #1 is at TDC (**Figure 13-39A**).
2. Check the camshaft alignment marks; if they are not aligned, rotate the crankshaft one full turn (**Figure 13-39B**) until they are aligned.
3. Refer to the service manual to identify the valves that are closed at this point. With a feeler gauge, measure and record the valve lash of those valves (**Figure 13-39C**).
4. Rotate the crankshaft one full turn with piston #1 again at TDC.
5. Measure and record the valve lash on the valves not measured in the previous step. Compare all measured clearances to specifications.
6. For any valves that do not have the proper lash, follow the rest of this procedure.
7. Rotate the camshaft so that the cam lobe for the valve needing adjustment is facing up.
8. Using a screwdriver, rotate the notch of the valve follower and shim assembly so that it is to the side of the camshaft.

9. While holding the camshaft in place, depress the valve lifter assembly.
10. Using a small screwdriver and a magnetic finger, remove the adjusting shim (Figure 13-39D).
11. Measure the thickness of the shim with a micrometer (Figure 13-39E).
12. Calculate the size of the required shim by adding the measured clearance to the size of the old shim. Then subtract the desired clearance from that total. That total is the required shim size. To correct excessive clearance, a thicker shim is installed. If reduced clearance is needed, a thinner shim must be installed.
13. Install the new shim and recheck the valve lash. Then move to the next valve that needs adjustment and repeat the process.
14. When all valves have been adjusted, reinstall the camshaft covers, timing belt cover, and anything else that has been removed.

Some engines rely on cam followers of different thicknesses to provide proper valve lash. To adjust lash on these engines, the valve clearance of all valves should be measured while the valves are closed. Once the lash adjustments have been determined, the camshaft needs to be removed. Then the thickness of the cam follower on the valves that were out of spec should be measured. The desired cam follower is determined in the same way as deciding the correct shim thickness. The thickness of the new follower should equal the thickness of the old follower plus the measured lash. The desired lash is then subtracted from that sum. The answer is the required thickness for the replacement follower.

$$\text{New lifter thickness} = (\text{Old lifter thickness} + \text{measured valve lash}) - \text{desired valve lash}$$

Figure 13-39 To adjust valve lash: (A) Rotate the crankshaft so that it is at TDC. (B) Check the camshaft alignment marks. (C) Measure and record the valve lash of the valves that are totally closed. (D) Use a small screwdriver and a magnetic finger to remove the adjusting shim. (E) Measure the thickness of the shim with a micrometer to determine the correct shim to install. *Courtesy of Toyota Motor Sales, U.S.A., Inc.*

Final Reassembly Steps

The final steps in engine assembly involve installing various covers, pulleys, sensors, and other related items that mount directly to the engine.

Coolant Drains and Plugs Make sure all coolant drains and plugs are installed in the block. Drains are normally threaded into the block with a thread sealant. This is also true for threaded plugs.

Timing Sensors Proper installation of the crankshaft and camshaft timing sensors is critical. Make sure to coat new O-rings with clean oil before they are installed (**Figure 13-40**). Some sensors have a specified gap that must be set during installation. Also

make sure that the trigger wheel for each sensor is properly aligned. Refer to the service manual.

Timing Cover When replacing the timing cover, remove the old gaskets and seals from the timing cover and block. Install the new seals using a press, seal driver, or hammer and a clean block of wood. When installing seals, be sure to support the underside of the cover to prevent damage. The gasket for the cover can be made of a variety of materials. Some require that a light coat of adhesive be applied to hold the gasket in place during assembly. Do not do this unless the gasket manufacturer recommends doing so. Position the gasket on the cover. Mount the cover onto the block and torque the bolts to specifications (**Figure 13-41**).

Vibration Damper Install the vibration damper onto the snout of the crankshaft using the proper tool. In most cases, the damper should bottom out against the oil slinger and timing sprocket. Make sure the woodruff key is in place. Some dampers are not pressed-fit onto the crankshaft. Be sure to install the large washer behind the damper-retaining bolt on these engines.

Mount the crankshaft pulley to the outside of the damper and tighten its mounting bolts to specifications. Often, the crankshaft will need to be held to prevent it from turning while the pulley's bolts are tightened. A special tool is normally required to do this.

Figure 13-40 A crankshaft position sensor.

Figure 13-41 A timing chain cover and water pump assembly.

Valve (Cam) Cover Before installing a stamped valve cover, make sure the cover's sealing flange is flat, then apply contact adhesive to the valve cover's sealing surfaces in small dabs. Mount the valve cover gasket on the valve cover and align it in position. If the gasket has mounting tabs, use them in tandem with the contact adhesive. Allow the adhesive to dry completely before mounting the valve cover on the cylinder head. Torque the mounting bolts to specifications.

Cast plastic and aluminum cam and valve covers normally have a rubber gasket. Do not apply an adhesive or sealant to the gasket unless instructed to do so. Start all of the mounting bolts before beginning the tightening sequence. Torque the bolts to specifications.

Water Pump In many cases, a coating of good waterproof sealer should be applied to both sides of the new gasket. Position the pump against the block. Install the mounting bolts and tighten them, in a staggered sequence, to specifications. Careless tightening could cause the pump housing to crack. After tightening, check the pump to make sure it rotates freely. Then, install the drive pulley onto the pump's shaft.

Oil Pan Before installing a stamped oil pan, check the flanges for warpage. Use a straightedge (**Figure 13-42**) or lay the pan, flange side down, on a flat surface with a flashlight underneath it to spot uneven edges. Carefully check the flange around the bolt holes. Minor distortions can be corrected with a hammer and block of wood. If the flanges are too bent to be repaired in this manner, the pan should be replaced. Once it has been determined that the flanges are flat, install the oil pan with a new gasket.

Figure 13-42 Checking the flatness of an oil pan flange. Courtesy of Detroit Gaskets

Cast pans are replaced if they are warped or damaged. Also, cast pans normally use a rubber gasket. The mounting bolts should be tightened in the proper sequence and to the specified torque.

Intake Manifold Before installing the manifold, thoroughly clean all of the sealing surfaces, bolt holes, and bolts. Inspect the surfaces for damage and repair or replace as necessary. Check the gaskets for any markings or installation instructions that may be stamped on them. Check the manufacturer's instructions for recommendations on the use of a supplementary sealant. Some intake manifold gaskets should be coated with a nonhardening sealer.

When installing an intake manifold on a V engine, it is wise to use guide bolts. These guides will make sure that the gaskets and the manifold are perfectly aligned before tightening them. They also prevent the manifold from shifting and rupturing the sealant. When tightening the bolts or nuts, make sure you tighten them to the proper torque and in the order specified.

On some V engines, there may be rubber or cork-rubber end seals for the front and the rear of the manifold. Before installing these seals, thoroughly clean all oil from the mating surfaces. Apply adhesive to the surface to hold the seals in place during installation. Once the intake manifold gaskets and seals are in place, apply a small bead (approximately $\frac{1}{8}$ inch) of silicone RTV to the point where the seals meet the gasket (**Figure 13-43**). Other engines may have a large one-piece intake manifold gasket with a splash guard. These are installed with the same care as other intake manifold gaskets.

Figure 13-43 On some engines, after the intake manifold gaskets and seals are in place, a small bead of RTV should be applied at the point where the seals meet the gasket.

Make sure the correct gasket is installed. Some intake gaskets purposely block off coolant passages to allow coolant to flow in a predetermined path through the engine. If these ports are not blocked off, the engine can overheat.

Thermostat and Water Outlet Housing Install the thermostat with the temperature sensor facing into the block. If the thermostat is installed upside down, the engine will overheat. Also install any coolant pipes and hoses that route the coolant in and out of the engine.

Exhaust Manifold When installing the exhaust manifold(s), tighten the bolts in the center of the manifold first to prevent cracking it. If there are dowel holes in the exhaust manifold that align with dowels in the cylinder head, make sure these holes are larger than the dowels. If the dowels do not have enough clearance because of the buildup of foreign material, the manifold will not be able to expand properly and may crack. Be sure to install all heat shields (**Figure 13-44**).

Flywheel or Flexplate Reinstall the engine sling. Raise the engine into the air on a suitable lift, and remove the engine stand mounting head. Set the assembled engine on the floor and support it on blocks of wood while attaching the flywheel or flexplate. Be sure to use the right flywheel bolts and lock washers. The bolts and washers are very thin. If normal bolts or washers are used, they may cause interference with the clutch disc or the torque converter. Manufacturers often recommend coating the bolts

Figure 13-44 Exhaust manifold and heat shield for a four-cylinder engine.

Figure 13-45 A flywheel holding and rotating tool.

with an adhesive. A flywheel holding tool is often required to tighten the bolts to specifications (**Figure 13-45**). Always follow the specified sequence while tightening. These may be TTY bolts.

CAUTION!

*On Honda and some other hybrids, extreme care must be taken when installing the rotor to the rear of the engine. The rotor assembly has very strong magnets. Anyone who has a pacemaker or other magnetically sensitive medical device should not handle the rotor assembly. The rotor should only be installed with the proper tools (**Figure 13-46**) and not with your hands. During installation, the rotor may be suddenly drawn toward the stator with great force, which can cause serious hand or finger injury.*

Clutch Parts If the vehicle has a manual transmission, install the clutch assembly (**Figure 13-47**). Make sure that the transmission's pilot bushing or bearing is in place in the rear of the crankshaft and that it is in good condition.

Using a clutch-aligning tool, or an old transmission input shaft, align the clutch disc. Then, tighten the disc and clutch pressure plate to the flywheel. Make sure the disc is installed in the right direction. There should be a marking on it that says "flywheel side." The flywheel may need to be held to tighten the bolts. Then install the bell housing if it was removed from the transmission. If the engine was removed with the transmission, reattach it now.

Figure 13-46 The special tools required to remove and install the rotor in a Honda hybrid.

Torque Converter On cars equipped with automatic transmissions, it is a good practice to replace the transmission's front pump seal before attaching it to the engine.

Install the torque converter, making sure that it is correctly engaged with the transmission's front pump. The drive lugs on the converter should be felt engaging the transmission front pump gear. Failure to correctly install the converter can result in damage to the

transmission's front pump. If the engine was removed with the transmission, reattach it now.

Motor Mounts Check the condition of all motor mounts and replace any that are damaged. Loosely attach the mounts to their location on the engine. This allows for easy alignment of the mounts while installing the engine into the vehicle. After the engine is aligned in the vehicle, the bolts should be tightened to specifications.

Other Parts There are many other parts that can be reinstalled before the engine is put back into the vehicle. These vary with the model of car. Always check with the service information before installing anything onto the engine. The following are a few of things that may be installed with the engine out of the vehicle:

- Starter
- Oil dipstick guide
- Engine coolant temperature sensor
- Engine oil pressure switch
- Engine oil level sensor
- Knock sensor
- Fuel injector
- Fuel rail
- Fuel pump
- PCV valve
- Engine wiring harness
- Camshaft timing control valve
- Drive belt tensioner

Flywheel and pressure plate friction surfaces must be free of dirt, grease, and oil prior to installation.

Figure 13-47 A typical clutch assembly.

- A/C compressor
- Generator assembly
- Drive belt
- Ignition coils
- Spark plugs
- Air cleaner assembly

INSTALLING THE ENGINE

Installing a computer-controlled engine can be a complex task requiring special procedures. Referring to the vehicle's service manual is absolutely essential for this procedure. Typically the procedure is the reverse of the removal procedure.

Installing an Engine into a FWD Vehicle

If the engine will be installed through the top, connect the engine to a sling and then connect the sling to the crane (**Figure 13-48**). Slowly lower the engine into the engine compartment. Guide the engine around all wires and hoses to make sure nothing gets damaged. As the engine approaches its position in the engine compartment, align the engine and transmission mounts. Then, lower the engine so you can connect the engine and transmission mounts. Now raise the vehicle to a good working height.

If the engine must be installed from under the car, mount the engine onto the engine cradle and dolly. Lift the vehicle on a hoist and position the engine under the engine compartment. Carefully lower the vehicle until the engine and transmission are properly positioned in the engine compartment. While doing this, guide all wires and hoses out of the way and make sure that the vehicle does not contact or rest on any part of the engine or transmission. With an engine hoist, raise the engine/transmission into place. Align the engine and transmission mounts and tighten the bolts. Remove the engine cradle and dolly. Then raise the vehicle to a good working height.

SHOP TALK

The mounting bolts for some engines should be installed and tightened according to a specified sequence. Excessive noise and vibration may result from not following this sequence. Always refer to the appropriate service information when installing an engine.

While working under the vehicle, align and tighten all remaining engine/transmission mounts. Install the drive axle shafts and hubs. Connect the exhaust

Figure 13-48 Equipment needed to install an engine from the top of a FWD vehicle.

Figure 13-49 Various connections for a transaxle.

manifold to the exhaust system. Install any heat shields that were removed when the engine was removed. Connect all linkages, lines, hoses, and electrical wiring to the transmission (**Figure 13-49**). Now reconnect all suspension and steering parts that were disconnected or removed. Check and replenish the fluid in the transaxle.

SHOP TALK

Many FWD vehicles require the powertrain cradle to be properly aligned after it is reconnected. This ensures correct steering and suspension alignment. After engine installation is completed, the vehicle's wheel alignment may need to be checked and adjusted.

Lower the vehicle and remove the engine support bar or sling. Install all splash shields that were removed, then install the tire/wheel assemblies.

Lower the vehicle so its weight is on the tires. Tighten the axle hub nuts. Connect the fuel lines with their clamps. Install the canister purge valves and related hoses. Make sure all connections are

secure. Now connect the engine wiring harness, ground straps, and all other electrical connectors and wires.

CAUTION!

*If working on a hybrid vehicle, make sure that the high-voltage system is isolated before making any connection. The high-voltage cables and connectors are orange in color (**Figure 13-50**).*

Connect all vacuum hoses. Then connect the throttle linkage and adjust it if necessary. Install the radiator, cooling fan(s), and overflow tank. Install the upper and lower radiator hoses. Then install the heater hoses. Hybrid vehicles have coolant hoses at the inverter; make sure these are properly tightened.

Install the automatic transmission fluid (ATF) cooler hoses to the transmission. Now install the A/C compressor with the drive belt, condenser fan shroud, and the electrical connectors for the fan motor and compressor clutch. Also connect the wiring to the

Figure 13-50 The high-voltage connectors and cables in a hybrid are colored orange for identification.

steering linkage. Then, reinstall the engine compartment support strut.

CAUTION!

On some vehicles the A/C compressor is powered by high voltage; make sure the high-voltage system is off. Also make sure that the power cables are secure in their mounting clamps.

Now install the air induction system and connect any remaining items, including the battery and cables. Check the engine for fuel leaks. Do this by turning the ignition switch to the ON position and allowing the fuel pump to run for a few seconds. Turn the power off and check for signs of leaks. If there are any leaks, repair them before proceeding.

Make sure everything that was removed when the engine was pulled is reinstalled and secure. If the vehicle's hood was removed, carefully reattach it. Refill the radiator with coolant, and bleed air from the system with the heater valve open. Visually check for leaks. Prelubricate the engine and make sure the oil level is correct. On hybrid vehicles, the high-voltage system should be activated after everything is connected.

CAUTION!

Once the high-voltage system is activated, lineman gloves should be worn while doing any under-the-hood work.

Customer Care

After the engine has been started and everything checked out, the wheels must be aligned. Failure to do this can make a customer very unhappy.

Installing an Engine in a RWD Vehicle

Connect the engine to a sling and then connect the sling to the crane. Place a transmission jack under the transmission to hold it in position. Now slowly lower the engine into the engine compartment. Guide the engine around all wires and hoses to make sure nothing gets damaged. As the engine approaches its position in the engine compartment, align the engine to the input shaft of the transmission or the torque converter hub into the front pump. Carefully wiggle the engine until the input shaft slides through clutch disc splines or the torque converter seats fully into the transmission. Install and tighten the transmission to engine bolts. Start the engine mount bolts into their bores; you may need to wiggle the engine some to do this. Once the mount bolts are in place, tighten them and remove the transmission jack and engine sling.

CAUTION!

Do not force the engine and transmission together with the bolts.

Raise the vehicle to a good working height and install all remaining engine and transmission mounts. Connect the exhaust manifold to the exhaust system. Install any heat shields that were removed when the engine was removed. Reconnect the fuel line from the fuel tank to the engine. Install the drive shaft if it was removed. Make sure to align it with the index marks made during removal. Connect all electrical connectors, hoses, and linkages that are accessible from under the vehicle. Reinstall any suspension and steering part that was removed.

Lower the vehicle so you can work under the hood. Mount the A/C compressor and connect all lines and electrical connectors. Install the radiator and the cooling fan(s) and connect the rest of the hoses for the cooling system. Connect all vacuum and other hoses. Now connect the throttle linkage and adjust it if necessary. Connect all remaining electrical connectors.

Connect any remaining disconnected fuel lines. Make sure all connections are secure. Connect the radiator and heater hoses; use new clamps. Connect the engine electrical harness to the PCM or firewall

Figure 13-51 Heater hose connecting points and the ECM wiring harness on the firewall.

connector (**Figure 13-51**). Connect the engine ground straps. Install the battery and connect the battery cables. Turn the ignition switch to the ON position and allow the fuel pump to run for a few seconds. Turn the power off and check for signs of leaks. If there are any leaks, repair them before proceeding.

Now install the air induction system and connect any remaining items, including the throttle cables and sensor. Fill the radiator with coolant and visually check for leaks. If the engine does not have oil in it already, add the specified amount of the proper type oil. Prime the oil pump of the engine and prepare the engine for startup. Install and align the hood.

Prelubrication

Not prelubing a new or rebuilt engine before starting it can cause premature bearing failure due to poor lubrication. Other parts such as pistons, rings, and cylinder walls need immediate lubrication to prevent scuffing, scoring, and damage. It can take as long as 5 minutes after the engine has started before oil is distributed through all of the vital parts of an engine. It is claimed that more than 80% of all engine wear occurs when an engine is first started.

These problems can be prevented by lubricating the parts as they are assembled and by forcing oil into the oil galleries. This is the purpose of prelubing. A **prelubricator** (**Figure 13-52**) forces oil throughout the engine before it is started. There are several ways to prelubricate, or prime, an engine. One of the most common ways is to use an air-operated prelubricator. The procedure for using this type of prelubricator follows:

1. Fill the oil filter with clean engine oil and install it.
2. If the oil pressure sensor is installed, remove it.

Figure 13-52 A prelubricator.

3. Install an appropriately sized fitting for the preluber in the sensor's bore.
4. Connect the preluber hose to the fitting.
5. Open the valve on the preluber.
6. Fill the container for the preluber with at least 2 quarts of clean oil.
7. Pump the handle on the preluber until all of the oil in it has moved into the engine.
8. Close the valve and disconnect the hose from the fitting.
9. Remove the fitting and install the oil pressure sensor. Be sure to tighten it to specifications.
10. Check the oil level in the engine and add oil as needed.

SHOP TALK

While prelubing an engine, make sure there is a continuous flow of the correct type of oil. If the preluber runs out of oil during priming, an air pocket can form within the engine's lubrication system.

Distributor-Driven Oil Pumps On engines with a distributor-driven oil pump, the engine can be primed by driving the oil pump with an electric drill. A fabricated oil pump drive shaft is chucked in an electric drill motor and inserted through the distributor bore into the drive on the oil pump. Take the valve covers off but loosely set them over the valves to control oil splash. Drive the oil pump with the electric drill. After running the oil pump for several minutes, remove the valve cover and check for oil flow to the rocker arms. If oil reached the cylinder head, the engine's

lubrication system is full of oil and is operating properly. If no oil reached the cylinder head, there is a problem with the pump, with an alignment of an oil hole in a bearing, or a plugged gallery.

Starting Procedure

On engines with an ignition distributor, set the ignition timing as accurately as possible before starting the engine. The timing can be properly set after it has been started by using an engine analyzer or timing light. Fill the gasoline tank with several gallons of fresh gasoline. Start the engine and run it at around 1,500 rpm. When the engine coolant reaches normal operating temperature, turn off the engine. Recheck all adjustments, ignition timing, and valve clearance. Look for signs of coolant or oil leaks.

Break-In Procedure

To prevent engine damage after it has been rebuilt and to ensure good initial oil control and long engine life, the proper **break-in** procedure must be followed. Make a test run at 30 mph and accelerate at full throttle to 50 mph. Repeat the acceleration cycle from 30 to 50 mph at least ten times. No further break-in is necessary. If traffic conditions will not permit this procedure, accelerate the engine rapidly several times through the intermediate gears during the road test. The objective is to apply a load to the engine for short periods and in rapid succession soon after the engine warms up. This action thrusts the piston rings against the cylinder wall with increased pressure and results in accelerated ring seating.

If a performance flat tappet camshaft and dual valve springs were installed in the engine, special break-in procedures should be followed. The inner valve springs must be removed before the engine is started and run. Doing this makes it easier for the lifters to rotate in their bores and establish an acceptable wear pattern. Immediately after the engine starts, bring the engine speed up to 2,000 to 2,500 rpm and hold it there for about 30 minutes. After that time, shut down the engine and change the oil and filter to remove all contaminants from the engine. Then reinstall the inner valve springs.

Relearn Procedures

The computer in most late-model vehicles must undergo a relearn or initialization procedure after

the battery has been reconnected. This procedure allows the computers to learn the condition of the engine and make adjustments according to the engine's restored condition. The last time the engine was run, the computer made adjustments based on the engine faults present. This procedure allows the computer to see that those faults were corrected. Initialization also resets the reference for the crankshaft position sensor and PCM. Always follow the manufacturer's procedures as outlined in the service manual.

Initialization is also necessary to reset the operating perimeters of many accessories, such as the power windows and the antitheft system. Devices like the clock and radio will need to be manually reset.

SHOP TALK

Hybrid vehicles have special initialization procedures. These systems automatically shut off the engine when the vehicle is stopped and restart it when certain conditions are present. In many cases, the PCM must know the exact position of the electric assist motor's rotor. If the PCM cannot recognize the rotor's position, the motor may not be able to run. In general, if initialization is not completed, the hybrid system will not work normally. The service information for the vehicle will give the procedures for each system that needs to be initialized.

Customer Care

After the engine has been totally checked over, return it to the owner with the following instructions:

1. Drive the vehicle normally but avoid sustained high speed during the first 500 miles (break-in period).
2. Do not allow the engine to sit idling for a long time.
3. Check the oil level frequently during the break-in period. It is not unusual to use 1 or 2 quarts of oil during this time.
4. The oil and oil filter should be changed at the end of the break-in time.
5. The cylinder head and intake manifold bolts may need to be retorqued.
6. Some adjustments, such as valve adjustments and ignition timing, may also need to be checked.

SHOP TALK

Some manufacturers recommend retorquing the cylinder head after a rebuilt engine has been run for the first time. With the engine at normal operating temperature, retighten each head bolt using the specified tightening sequence. If the engine has an aluminum head or block, do not retorque the bolts until the engine has cooled. On some engines it may be necessary to retorque the head, again, after a specified time or mileage interval. Always follow the manufacturer's recommendations.

CASE STUDY

A four-cylinder DOHC engine has just been rebuilt. During the initial running of the engine, it runs quite rough. This is normal until everything gets seated. However, the condition becomes worse the more the engine runs. Slight adjustments to the ignition timing do not help the condition. A visual inspection reveals nothing loose or disconnected. Each hose and wire is traced to make sure it is connected to the proper fitting and terminal.

Because it seems that the engine is running on only three cylinders, a cylinder leakage test is performed. The results indicate excessive leakage past the #4 intake valve. In an attempt to visually locate the problem, the intake cam cover is removed. A look at the camshaft reveals that the #4 intake lobe is worn. This was a new camshaft. Was it defective? Was it not hardened properly? Did something else cause this?

Further visual inspection reveals that the shim used to set valve lash was not fully seated in its cup. The edge of the shim was working like a knife, cutting off the metal from the lobe. The initial rough running of the engine was caused by the shim preventing the valve from fully closing. The condition worsened as the lobe was cut away.

The oil was changed and a new camshaft and shim were installed to correct the problem.

Yield

SUMMARY

- Elasticity means that a bolt can be stretched a certain amount and it returns to its original size when the load is reduced.
- Bolt yield means that a stretched bolt takes a permanent set and never returns to normal.
- Some fasteners are intentionally torqued into a yield condition. These torque-to-yield (TTY) bolts are designed to stretch when properly tightened. When a bolt is stretched to its yield point, it exerts its maximum clamping force. TTY bolts should not be reused.
- Gaskets serve as sealers, spacers, wear insulators, and vibration dampeners.
- Gaskets can be made of paper, fiber, steel, cork, synthetic rubber, and combinations of these materials.
- General recommendations for installing gaskets include: Never reuse old ones; handle new ones carefully; use sealants only when instructed; thoroughly clean all mating surfaces; and use the right gasket in the right position.
- Cylinder head gaskets must seal all of the combustion chambers and the coolant and oil passages between the head and the block.
- Common causes of cylinder head gasket failure include improper installation, overheating, hot spots, and detonation or preignition.
- Adhesives are used to hold a gasket in place during component assembly.
- Bolts that pass through a liquid passage should be coated with Teflon thread or a brush-on thread sealant.
- Silicone gasketing, of which RTV is the best known, is used on oil pans, valve covers, thermostat housing, timing covers, and water pumps.
- Anaerobic formed-in-place sealants are used for both thread locking and gasketing.

- Oil seals keep oil and other fluids from escaping around a rotating shaft.
- All engines with mechanical lifters have some method of adjustment to bring valve lash (clearance) back into specification.
- The steps in final engine assembly involve installing various engine covers, prelubing the engine, and installing manifolds and related items that mount directly to the engine assembly.
- The best method of prelubricating an engine under pressure without running it is to use a prelubricator, which consists of an oil reservoir attached to a continuous air supply.
- A proper break-in procedure is necessary to ensure good initial oil contact and long engine life.

REVIEW QUESTIONS

1. *True or False?* Make sure you locate and adhere to the “wet” torque specs when tightening a bolt that has been lubricated with oil or any other liquid.
2. What does it mean when a bolt is stretched into yield?
3. Name some applications of hard gaskets.
4. Where are flexible sealers most often used?
5. What are the major differences between aerobic and anaerobic sealants?
6. Which of the following statements is incorrect?
 - a. Cylinder head bolts must be tightened to the proper amount of torque.
 - b. Most cylinder head bolts are tightened in a sequence that starts on one end.
 - c. On some engines, the head bolts are retorqued after the engine has been run and is hot.
 - d. Many engines use head bolts of different lengths.
7. *True or False?* Valve lash is adjusted in many different ways; however, on most OHV engines with hydraulic lifters the clearance is set when the lifter is sitting on the nose of the cam lobe.
8. Which of the following statements about the purpose of a cylinder head gasket is *not* true?
 - a. It seals intake stroke vacuum, combustion pressure, and the heat of combustion.
 - b. It prevents coolant leakage and resists rust, corrosion and, in many cases, meter coolant flow.
 - c. It allows for lateral and vertical head movement as the engine heats and cools.
 - d. It meters lubricating oil onto the engine’s cylinder walls.
9. *True or False?* The computer in most late-model vehicles must undergo a relearn or initialization procedure after the vehicle’s battery has been disconnected and reconnected.
10. Graphite is _____.
 - a. an anaerobic substance
 - b. an RTV
 - c. an aerobic substance
 - d. none of these
11. Which of the following are considered soft, cut gaskets?
 - a. paper gaskets
 - b. cork gaskets
 - c. cork/rubber gaskets
 - d. all of the above
12. What material is typically not used to form a rear main bearing oil seal?
 - a. polyacrylate
 - b. RTV
 - c. silicone synthetic rubber
 - d. Viton
13. Which of the following statements about preparing to assemble an engine is *not* true?
 - a. Discard and replace all bolts that are damaged.
 - b. Identify what bolts go into the specific bores.
 - c. Use a thread locker on all bolts.
 - d. Clean bolt and cylinder block threads with a thread chaser or tap.
14. On nearly all hybrid vehicles, how can you identify the high-voltage cables and connectors?
15. *True or False?* Some crankshaft and camshaft timing sensors have a specified gap that must be set during installation.

ASE-STYLE REVIEW QUESTIONS

1. Technician A says that TTY bolts can be used after they were removed if there are no signs of distortion or stretching. Technician B says that head bolts that pass through a coolant passage

- should be coated with a nonhardening sealer prior to installing them. Who is correct?
- Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- Technician A uses adhesives to hold gaskets in place while installing them. Technician B uses RTV sealant on all surfaces that are prone to leaks. Who is correct?

 - Neither A nor B

LUBRICATING AND COOLING SYSTEMS

OBJECTIVES

- Name and describe the components of a typical lubricating system.
- Describe the purpose of a crankcase ventilation system.
- Describe the operation of the cooling system.
- List and describe the major components of the cooling system.
- Describe the function of the water pump, radiator, radiator cap, and thermostat in the cooling system.
- Diagnose the cause of engine overheating.
- Explain why today's engines are concerned with engine operating temperatures.
- Test and service the cooling system.

The life of an engine largely depends on its lubricating and cooling systems. If an engine does not have a supply of oil or cannot rid itself of high temperatures, it will be quickly destroyed.

LUBRICATION SYSTEM

An engine's lubricating system does several important things. It holds an adequate supply of oil to cool, clean, lubricate, and seal the engine. It also removes contaminants from the oil and delivers oil to all necessary areas of the engine. The main components of a typical lubricating system (**Figure 14-1**) are described here.

Engine Oil

Engine oil is specially formulated to lubricate and cool engine parts. The moving parts of an engine are fed a constant supply of oil. Engine oil is stored in the oil pan or sump. The oil pump draws the oil from the sump and passes it through a filter where dirt is removed. The oil is then moved throughout the engine via oil passages or galleries (**Figure 14-2**). After circulating through the engine, the oil returns to the sump.

Oil Pump

The oil pump is the heart of the lubricating system. Just as the heart in a human body circulates blood through veins, an engine's oil pump circulates oil through passages in the engine. The oil pump pickup is a line from the oil pump to the oil stored in the oil pan. It usually contains a filter screen, which is submerged in the oil at all times (**Figure 14-3**). The screen serves to keep large particles from reaching the oil pump. This screen should be cleaned any time the oil pan is removed. The pickup may also contain a by-pass valve that allows oil to enter the pump if the screen becomes totally plugged.

Because the oil pump is a positive displacement pump, an oil **pressure relief valve** is used to prevent excessively high system pressures from occurring as engine speed is increased. Once oil pressure exceeds a preset limit, the spring-loaded pressure relief valve opens and allows the excess oil to bypass the rest of the system and return directly to the sump.

Chapter 11 for a detailed discussion of oil pumps.

Figure 14-1 The major components of an engine's lubrication system.

Figure 14-2 Direction of oil flow through this V-10 engine. *Courtesy of Chrysler LLC*

Oil Pan or Sump

The oil pan is attached to the bottom of the engine block. It serves as the reservoir for the engine's oil. It is designed to hold the amount of oil that is needed to lubricate the engine when it is running, plus a reserve. The oil pan also helps to cool the oil through its contact with the outside air.

Oil is drawn out by the oil pump. The pump pressurizes the oil and sends it to the main oil gallery where it is channeled off to the bearing surfaces and the valve train. The oil drains back into the pan. This

Figure 14-3 An oil pickup and screen.

process maintains a flow of oil throughout the engine. This is often referred to as a **wet sump** oil system because the sump always has oil in it.

Pan Baffles In a wet sump system, the oil can slosh around during hard cornering or braking. During these times it is possible for the oil to move away from the oil pump's pickup. This will cause a temporary halt in oil flow through the engine, which can destroy it. Sloshing also can affect the rotation of the crankshaft. As the crankshaft rotates through a thick puddle of oil, it meets resistance and slows down. To help prevent sloshing, many engines have baffles in the oil pan to limit the movement of the oil.

Figure 14-4 An oil pan and external pump for a dry sump system. Courtesy of Dailey Engineering

Dry Sump To eliminate the possibility of oil sloshing, some OEM engines are fitted with a **dry sump** oil system, as are most race engines. In a dry sump system, the oil pan does not store oil. The dry oil pan merely seals the bottom of the crankcase. The oil reservoir is a remote container set apart from the engine. Rather than having a single path for oil travel, dry sump pumps can feed oil directly to the crankshaft, valve train, and turbocharger. Normally one external oil pump (**Figure 14-4**) is used; however, some systems have two pumps. The second pump pulls all the oil out of the sump and returns it to the reservoir. This pump also lowers the pressure inside the crankcase.

Dry sump systems provide immediate oil delivery to critical areas of the engine. They also prevent oil starvation caused by acceleration, braking, and cornering forces. Because the dry sump is smaller than a wet sump, the engine can be placed lower in the frame to improve overall handling.

Oil Filter

All of the oil that leaves the oil pump is directed to an oil filter (**Figure 14-5**). This ensures that small particles of dirt and metal suspended in the oil will not reach the close-fitting engine parts. This stops those impurities, which can cause premature wear, from circulating through the engine. Filtering also increases the usable life of the oil. The filter assembly threads directly onto the main oil gallery tube. The oil from the pump enters the filter and passes through the element of the filter. From the element, the oil flows back into the engine's main oil gallery.

An oil filter assembly is typically a disposable metal container filled with a special type of treated paper or other filter substance (cotton, felt, and the like). Some engines have a separate cartridge that fits into a metal casing (**Figure 14-6**). The filter is usually mounted on

Figure 14-5 An oil filter being installed on an engine block. Courtesy of Honeywell International Inc.

Figure 14-6 An oil filter assembly with a replaceable element. The oil in the oil filter can be drained by removing the drain plug before replacing the element. Courtesy of Toyota Motor Sales, U.S.A., Inc.

Figure 14-7 Oil lines carry the engine oil in and out of this remote filter before it moves through the engine to lubricate parts. *Courtesy of BMW of North America, LLC*

and sealed to an adapter bolted to the block. However, it may be attached to the timing cover or remotely mounted with oil lines connecting the filter to the oil galleries in the block (**Figure 14-7**).

Some oil filters have an antidrainback valve. The purpose of this valve is to prevent oil drainage from the filter when the engine is not running. This allows for a supply of filtered oil as soon as the engine is started and has oil pressure.

The oil filtration system used on today's vehicles is commonly referred to as a full-flow system. All of the oil going to the engine bearings goes through the filter first. However, should the filter become plugged, a relief valve in the filter will open and allow oil to bypass and go directly to the bearings (**Figure 14-8**). This provides the bearings and the rest of the engine with necessary, though unfiltered, lubrication.

Oil Coolers

To control oil temperature, many diesel, high-performance, and turbocharged engines have an external engine oil cooler (**Figure 14-9**). Oil flows from the pump through the cooler and then to the engine. An oil cooler looks like a small radiator mounted near the front of the engine or within the radiator. Heat is removed from the oil as engine coolant flows through or around the cooler and air passes through it. Hot oil mixed with oxygen breaks down (oxidizes) and forms carbon and varnish. The higher the temperature, the faster these deposits build. An oil cooler helps keep the oil at its normal operating temperature.

Figure 14-8 Oil flow through the filter. *Courtesy of Ford Motor Company*

Engine Oil Passages or Galleries

From the filter the oil flows into the engine oil galleries. These galleries consist of interconnecting passages that have been drilled completely through the engine block during manufacturing. The outside ends of the passages are blocked off so the oil can be routed through these galleries to various parts of the engine. The crankshaft also contains oil passages (oilways) to route the oil from the main bearings to the connecting rod bearing surfaces. Engines with a remote oil filter, an oil cooler, or a dry sump system have external oil lines that move the oil to designated areas.

Oil Seals and Gaskets

Seals and gaskets are used throughout the engine to prevent both external and internal oil leaks. The most

Figure 14-9 To control oil temperatures, some engines are fitted with a water-cooled oil cooler.

common materials used for sealing are synthetic rubber, soft plastics, fiber, and cork. In critical areas these materials might be bonded to a metal.

Dipstick

The dipstick is used to measure the level of oil in the oil pan. The end of the stick is marked to indicate when the engine oil level is correct. It also has a mark to indicate the need to add oil to the system.

Oil Pressure Indicator

All vehicles have an oil pressure gauge and/or a low-pressure indicator light. Oil gauges are either mechanically or electrically operated and display the actual oil pressure of the engine. The indicator light only warns the driver of low oil pressure.

In a mechanical gauge, oil travels up to the back of the gauge where a springy, flexible, hollow tube, called a Bourdon tube, uncoils as the pressure increases. A needle attached to the Bourdon tube moves over a scale to indicate the oil pressure.

Most pressure gauges are electrically controlled. An oil pressure sensor or sending unit is screwed into an oil gallery. As oil passes through an oil pressure sender (**Figure 14-10**), it moves a diaphragm, which is connected to a variable resistor. This resistor changes the amount of current passing through the circuit. A gauge on the dashboard reacts to the current and moves a needle over a scale to indicate the oil pressure, or the current is translated into a digital reading on the gauge.

Warning light systems are basically simple electrical circuits. The indicator light comes on when the circuit is completed by a sensor. This sensor has a

Figure 14-10 As oil pressure changes, the resistance in the oil pressure gauge circuit and the reading on the gauge change accordingly.

Figure 14-11 An oil pressure sensor for a warning gauge.

diaphragm connected to a switch inside the sensor. Under normal conditions, the sender switch is open. When oil pressure falls below a certain level, the reduction of pressure causes the diaphragm to move and close the sender switch (**Figure 14-11**), which completes the electrical circuit. When this happens, electricity flows and turns on the warning light on the dashboard.

Oil Level Indicators Some late-model vehicles are equipped with an electronic oil level indicator. When the oil level in the oil pan drops below a

predetermined level, a sensor completes the warning lamp circuit and the lamp lights.

ENGINE LUBRICATION DIAGNOSIS AND SERVICE

Other than engine destruction, engine lubrication problems can cause other engine concerns, such as noise, exhaust smoke, and the need to add oil to the crankcase.

Engine Oil

The level of the oil in an engine should be checked periodically. The condition of the oil should be noted at that time as well. Engine oil is specially formulated to lubricate and cool engine parts. Changing the engine's oil is a common preventive maintenance procedure.

Chapter 9 for the correct procedure for conducting and interpreting an oil pressure test.

If the oil pump or its pressure regulator valve proves to be faulty, it should be replaced.

Chapter 11 for the correct procedure for inspecting and installing an oil pump.

Chapter 7 for the correct procedure for changing the oil and oil filter.

Oil Filter The oil filter is normally changed when the oil is changed. There are several designs of oil filters; always use the type of filter that is recommended for the vehicle you are working on. Some oil filters have a drain plug in their housing that should be used to drain the engine's oil. The drain pipe is normally included with the replacement filter cartridge.

SHOP TALK

On some engines, the oil filter should be removed before opening the drain plug at the sump. Doing this allows oil to flow freely from the crankcase.

WARNING!

Used oil and oil filters must be disposed of properly and in accordance to local, state, and federal laws.

Oil Pump

The oil pump seldom is the cause for lubrication problems. However, like any other engine part, it can

go bad. The best way to check the performance of an oil pump is to conduct an oil pressure test. This test will not only check the oil pump, but it also will evaluate the rest of the lubrication system.

Oil Passages, Galleries, and Lines

All oil passages, galleries, and lines should be thoroughly cleaned and flushed during and after an engine has been overhauled.

Oil Consumption

Excessive oil consumption can result from external and internal leaks or worn piston rings, valve seals, or valve guides. Internal leaks allow oil to enter the combustion chamber where it is burned. Blue exhaust smoke is an indication that an engine is burning oil.

If the valve guides are worn or the valve seals are worn, cracked, or improperly installed, oil will be drawn into the cylinder during the intake stroke. If there are worn or broken piston rings or worn cylinder walls, the affected cylinders will have low compression. The oil in the cylinder also tends to foul the spark plugs, which will cause misfires, high emissions, and possible damage to the catalytic converter.

External leaks are another common cause of excessive oil consumption. These leaks can occur at the valve or cam cover gasket, oil filter, front and rear seals, oil pan gasket, and timing gear cover. Fresh oil on the clutch housing, oil pan (**Figure 14-12**), edges of valve covers, external oil lines, crankcase filler tube, or at the bottom of the timing gear or chain cover usually indicates that the leak is close to or above that point.

When crankcase pressure is abnormally high, oil is forced out through joints that normally would not leak. Pressure develops when blowby becomes excessive or when a positive crankcase ventilation (PCV)

Figure 14-12 The presence of oil and dirt buildup around the oil pan indicates a leaky pan gasket.

system is not working properly. **Blowby** is a term used for the gases that escape the combustion chamber and enter the crankcase. These gases leak between the piston rings and cylinder walls. Blowby gases are normally pressurized air-fuel mixture and/or pressurized exhaust gases. The PCV system provides a continuous flow of fresh air through the crankcase to relieve the pressure and to prevent the formation of corrosive contaminants (**Figure 14-13**). PCV valves are designed for a particular engine's operating characteristics. Using the wrong valve can cause oil consumption as well as other problems. If the PCV valve or connecting hoses become clogged, excessive pressure will develop in the crankcase. The pressure can cause oil to leak past gaskets and seals. It might also

Figure 14-13 The operation of a PCV system.

force oil into the air cleaner or cause it to be drawn into the intake manifold.

Oil Usage Even the smallest oil leak can cause excessive oil consumption. Losing three drops of oil every 100 feet (30.48 m) equals 3 quarts (2.8 liters) of oil lost every 1,000 miles. Typically, new engines use less than a quart (0.946 L) of oil every 6,000 miles (9,656 km). As the engine wears, its oil usage increases. It is not unusual for a high-mileage engine to use a quart (0.946 L) of oil every 1,000 miles (1,609 km).

Sludge

The typical sign of poor maintenance is the buildup of yellow sludge inside the engine. **Sludge** (**Figure 14-14**) results from the oxidation of oil. When oil oxidizes, chemical compounds in the oil begin to chemically break down and solidify, forming a gel substance. The gelled oil cannot circulate through the engine and collects on engine parts. This buildup of sludge can also block normal lubrication paths. A sludged engine is a sick engine and parts will fail due to poor lubrication (**Figure 14-15**).

Initial signs of sludge buildup include lower than normal oil pressure, increased fuel consumption, increased emissions, and poor driveability. These are caused by poor lubrication and the heat stored by the gel.

Sludge begins to form at the top of the engine and in the oil pan. As the engine is run with the broken-down oil, more sludge is formed and collects on the various parts of the engine.

A slight buildup of sludge on the inside of the oil filler cap is normal. This is caused by condensation. However, if there is quite a bit of sludge, there is probably sludge throughout the engine. Excessive sludge

Figure 14-14 Sludge buildup on the lower parts of an engine.

Figure 14-15 Damage to this main bearing was caused by a lack of oil. *Courtesy of Dana Corporation*

can also be caused by a plugged PCV hose or valve. Because the PCV purges the crankcase of vapor and moisture, a plugged system will allow condensation to build up and contaminate the oil. If the sludge on the filler cap is white, suspect a blown head gasket. The whitish gel is caused by coolant mixing with the oil. To verify this condition, use a combustion leak detector or run a cylinder leakage test.

Often, sludge can be removed by flushing the system. However, if the buildup is great, the engine should be torn down and cleaned.

SHOP TALK

Many late-model engines have a sludging problem. There are several reasons for this: These engines have long oil change intervals, use low-viscosity oils, have high operating temperatures, and run with a very lean mixture. Manufacturers of the affected engines have policies and procedures for dealing with these problem engines. Always check with the manufacturer when faced with a sludged engine.

Flushing the System

Flushing the lubrication system on a periodic basis or removing sludge is recommended by some manufacturers. However, there are others that recommend not to flush the engine. Flushing involves running a solvent through the engine and then draining the system. The ways to do this vary, as do the solvents used. Theoretically, flushing should help. The concern of those that do not recommend flushing is simply that the solvents may loosen up some dirt or sludge that will not drain out with the

oil. These contaminants can block passages and restrict oil flow. Obviously, the manufacturers of the solvents and flushing equipment disagree.

Oil flushing solvents are available in containers that are added to the engine's oil before an oil change. The engine is run for about one-half hour and then the oil and filter are changed. Flushing machines connect to the filter housing and the drain plug port after the oil has been drained. A heated solution is pumped through the oil reservoir, passages, oil pump, and up into the valve train. The solvent back flushes the oil pump and pickup screen and breaks up and dissolves the sludge. The remains are drawn out by a vacuum. After flushing, a new oil filter is installed and clean oil is added to the engine.

Oil Cooler

If an engine has an external oil cooler, it and its lines should be inspected for leaks. If leaks are evident, the lines and/or cooler should be replaced. The cooler assembly should be flushed or replaced whenever there is a sludge buildup in the engine. If the engine was rebuilt, the cooler should be replaced and the lines cleaned. This is recommended because metal debris that may be trapped in the cooler can become dislodged after the engine has been run and cause oil starvation.

COOLING SYSTEMS

Today's engines create a tremendous amount of heat. Most of this heat is generated during combustion. Metal temperatures around the combustion chamber can run as high as 1,000°F (537.7°C). This heat can destroy the engine and must be removed. This is the purpose of the engine's cooling system (**Figure 14-16**). The system must also allow the engine to quickly warm up to a desired operating temperature and keep it there regardless of operating conditions.

Heat is removed from around the combustion chambers by a heat-absorbing liquid (coolant) circulating inside the engine. Coolant then flows to the radiator where the coolant's heat is transferred to the outside air. A pump moves the coolant through the engine block and then through the cylinder head. A thermostat is used to control operating temperature. When the coolant temperature is below the desired operating temperature, the thermostat is closed, which allows the coolant to recycle through the engine. When normal operating temperatures are reached, the thermostat opens to allow the coolant to flow to the radiator. The coolant flows to the top of the radiator and loses heat as it flows down through the

Figure 14-16 Major components of a liquid-cooling system. Arrows indicate the coolant flow.

radiator. Ram air and the airflow from the cooling fan move through the radiator and cool the coolant. The cooled coolant leaves the radiator and enters the water pump and then is sent back through the engine.

Coolant

Chapter 7 for a detailed discussion of engine coolant.

Engine coolant is a mixture of water and anti-freeze/coolant. Engine coolant has a higher boiling temperature and a lower freezing point than water. The exact boiling or freezing temperatures depend on the mixture. The typical recommended mixture is a 50/50 solution of water and antifreeze/coolant.

Thermostat

The **thermostat** controls the minimum operating temperature of the engine. The maximum operating

temperature is controlled by the amount of heat produced by the engine and the cooling system's ability to dissipate the heat.

A thermostat is a temperature-responsive coolant flow control valve. It controls the temperature and amount of coolant entering the radiator. While the engine is cold, the thermostat remains closed (**Figure 14-17A**), allowing coolant to only circulate in the engine. This allows the engine to uniformly warm up. When the coolant reaches a specified temperature, the thermostat begins to open and allows coolant to flow to the radiator. The hotter the coolant gets, the more the thermostat opens (**Figure 14-17B**), sending more coolant to the radiator. Once the coolant moves through the radiator, it reenters the water pump. From there it is pushed through the passages in the engine and the cycle starts again.

The thermostat permits fast engine warmup. Slow warmup causes condensation in the crankcase, which can cause the formation of sludge. The thermostat also keeps the coolant above a specific minimum temperature to ensure efficient engine performance. Thermostats must start to open at a specified

Figure 14-17 (A) Thermostat closed; (B) thermostat open.

temperature—normally 3°F (1.6°C) above or below its temperature rating. It must be fully opened at about 20°F (−7°C) above the “start to open” temperature.

Today’s thermostats have a specially formulated wax and powdered metal pellet contained in a heat-conducting copper cup that has a piston inside a rubber boot. Heat causes the wax to expand, forcing the piston outward, which opens the thermostat’s valve. The pellet responds to temperature changes and opens and closes the valve to control coolant temperature and flow. Today’s thermostats are also designed to slow the flow of coolant when they are open. This prevents the coolant from moving too quickly through the engine. Fast-moving coolant may not have enough time to absorb heat and, therefore, overheating can result.

Most thermostats are located on the top and front of an engine (**Figure 14-18**). The heat element fits into a recess in the block where it is exposed to hot coolant. The top of the thermostat is then covered by the water outlet housing, which holds it in

Figure 14-18 A typical thermostat located in the water outlet.

place and provides a connection to the upper radiator hose.

Water Pump

The heart of the cooling system is the water pump. Its job is to move the coolant through the system. Typically the water pump is driven by the crankshaft through pulleys and a drive belt (**Figure 14-19** and **Figure 14-20**). On some engines the pump is driven by the camshaft, timing belt or chain, or an electric motor. No matter how these units are driven, they all basically work the same way. The pumps are centrifugal-type pumps (**Figure 14-21**) with a rotating impeller to move the coolant. The shaft is mounted in the water pump housing and rotates on bearings. The pump has a seal to keep the coolant from passing through it. The inlet of the pump connects to the lower radiator hose, and its outlet connects to the engine block.

Figure 14-19 A water pump bolted to the front of an engine.

Figure 14-20 This water pump is driven by the timing belt.

Figure 14-21 An impeller-type water pump.

Radiator

The radiator is basically a heat exchanger, transferring heat from the engine to the air passing through it. The radiator itself is a series of tubes and fins (collectively called the core) that expose the coolant's heat to

Figure 14-22 A radiator core is made of a series of tubes and fins that expose the coolant's heat to as much surface area as possible.

as much surface area as possible (**Figure 14-22**). Attached to the sides or top and bottom of the core are plastic or aluminum tanks (**Figure 14-23**). One tank holds hot coolant and the other holds the cooled coolant. Cores are normally comprised of flattened aluminum tubes surrounded by thin aluminum fins. The fins conduct the heat from the tubes to the air flowing through the radiator. Most radiators have drain petcocks or plugs near the bottom. Coolant is added at the radiator cap or the recovery tank.

The efficiency of a radiator depends on its basic design, the area and thickness of the core, the amount of coolant going through the radiator, and the temperature of the cooling air. Today's radiators are designed to limit the amount of heat dissipated; this keeps the coolant somewhat hot at all times. Keeping engines operating at a high temperature is necessary to maintain low emission levels.

Radiators are normally based on one of two designs: cross flow or down flow. In a cross-flow radiator, coolant enters on one side, travels through tubes, and collects on the opposite side. In a down-flow radiator, coolant enters the top of the radiator and is drawn downward by gravity. Cross-flow radiators are seen most often on late-model cars because all the coolant flows through the fan's airstream, and the design allows for body designs with lower hood profiles.

Transmission Cooler Radiators used in vehicles with automatic transmissions have a sealed heat exchanger, or a form of radiator, located in the coolant outlet tank

Figure 14-23 The core of a radiator is placed between plastic or aluminum tanks. One tank may contain the oil cooler for an automatic transmission and/or the engine.

of the engine's radiator. Metal or rubber hoses carry hot automatic transmission fluid to the oil cooler. The coolant passing over the sealed oil cooler cools the fluid, which is then returned to the transmission. Cooling the transmission fluid is essential to the efficiency and durability of an automatic transmission.

Radiator Pressure Cap

Radiator caps (**Figure 14-24**) keep the coolant from splashing out of the radiator. They also serve a very important role in keeping the coolant's temperature

within a desired range. It does this by keeping the coolant pressurized to a specified level.

The pressure raises the boiling point of the coolant. For every pound of pressure put on the coolant, the boiling point is raised about $3\frac{1}{4}$ degrees Fahrenheit (1.8°C). Today's caps normally are designed to hold between 14 and 18 psi (93 and 123 kPa). This allows the coolant to reach higher-than-normal temperatures without boiling. This also allows the coolant to absorb more heat from the engine and more heat to transfer from the radiator core to outside air. This is due to a basic law of nature that states that the greater the heat difference is between two objects, the faster the heat of the hotter object will move to the cooler object.

The pressure in the system is regulated by a pressure relief or vent valve in the radiator cap (**Figure 14-25**). When the cap is tightened on the radiator's filler neck, it seals the upper and lower sealing surfaces of the neck. The pressure relief valve is compressed against the lower seal. Coolant pressure builds up as the temperature of the coolant rises. When the pressure reaches the pressure rating of the cap, it pushes up on the spring in the pressure relief valve. This opens the valve and allows excess pressure to exit the radiator through a bore between the upper and lower seals. The bore is connected, by a tube, to the expansion or recovery tank. When enough pressure has been released

Figure 14-24 A radiator cap on a late-model engine.

Figure 14-25 Parts of a radiator pressure cap assembly. Courtesy of Chrysler LLC

to drop system pressure below the cap's rating, the spring will close the pressure relief valve. When the coolant cools, its pressure drops. The low pressure opens the vacuum relief valve. The low pressure then draws coolant from the expansion tank to refill the radiator.

All radiator caps are designed to meet SAE standards for safety. This standard specifies that there shall be a detent or safety stop position allowing pressure to escape from the system without allowing the hot coolant to blow out of the radiator's neck. Only after all pressure has been relieved should the cap be removed from the filler neck.

WARNING!

Never remove the radiator cap from a hot engine. Doing so can allow hot coolant and steam to shoot out and seriously burn you.

Radiator pressure cap specifications require that the cap must not leak below the low limit of the pressure range and must open above the high limit. They are labeled by the amount of pressure they should hold. For domestic vehicles, the pressure is stated in psi or kPa. Normally kPa ratings are expressed as a number times 100 kPa, for example: 1.3×100 kPa. This is a 130 kPa cap.

Radiator caps for some imported vehicles may have different markings. Some may be marked "0.9 Bar." This indicates that the pressure rating of the cap is 0.9 times normal atmospheric pressure. Because atmospheric pressure is 14.7 psi, a 0.9 cap has a pressure rating of about 13.2 psi (14.7×0.9). Another common rating is "100." The "100" indicates that the pressure rating of the cap is 100% of atmospheric pressure, or 14.7 psi.

Figure 14-26 A coolant expansion tank.

Expansion Tank All late-model cooling systems have an **expansion** or **recovery tank** (Figure 14-26). Cooling systems with expansion tanks are called closed-cooling systems. They are designed to catch and hold any coolant that passes through the pressure cap. As the engine warms up, the coolant expands. This eventually causes the pressure cap to release. The coolant passes to an expansion tank. When the engine is shut down, the coolant begins to shrink. Eventually, the vacuum spring inside the pressure cap opens and the coolant in the expansion tank is drawn back into the cooling system.

Hoses

Coolant flows from the engine to the radiator and from the radiator to the engine through radiator hoses. The hoses are usually made of butyl or neoprene rubber hoses to cushion engine vibrations and prevent damage to the radiator.

A hose is typically made up of three parts: an inner rubber tube, some reinforcement material, and an outer rubber cover. Different covers and reinforcements are used depending on the application of the hose. All three parts are bonded together. Basically the difference in hose construction lies in what the hose will carry, where it is located, and the temperature and pressure it will face. Cooling system hoses must be able to endure heavy vibrations and be resistant to oil, heat, abrasion, weathering, and pressure.

Most vehicles have at least four hoses in the cooling system; some have five or more (Figure 14-27). Two small diameter hoses send hot coolant from the water pump to the heater core and back. Two larger diameter hoses move the coolant from the water pump to the radiator and back into the engine block. The fifth hose is a small diameter bypass hose that

Figure 14-27 Routing of coolant through the cooling system hoses. Courtesy of Chrysler LLC

allows coolant to circulate within the engine when the thermostat is closed. This hose is not required on all engines because the bypass feature is built into the engine block or cylinder head.

Hoses are sized according to their inside diameter. For example, common heater hoses are $\frac{5}{8}$ or $\frac{3}{4}$ inch. Radiator hoses are larger and have reinforcements that allow them to withstand about six times the normal operating pressure of the cooling system.

Radiator hoses are seldom straight tubes. They typically must bend or curve around parts to make a good connection without kinking. Straight hoses are not used because bending will cause them to collapse at the bend, causing a restriction. Most original equipment radiator hoses are molded to a specific shape to fit specific applications. Lower radiator hoses are normally reinforced with wire to prevent them from collapsing due to the suction of the water pump.

Heater hoses are made with reinforcements to help keep their shape. Some applications require a molded shape due to complex routing or curves. Some applications can use straight pieces of hose; however, most have bends.

Water Outlet The water outlet is the connection between the engine and the upper radiator hose through which hot coolant from the engine is pumped

into the radiator. It has been called a gooseneck, an elbow, an inlet, an outlet, or a thermostat housing. Generally, it covers and seals the thermostat and, in some cases, includes the thermostat bypass. Most water outlets are made of cast iron, cast aluminum, or stamped steel.

Water Jackets Hollow passages in the block and cylinder heads surround the areas closest to the cylinders and combustion chambers (**Figure 14-28**). Included in the water jackets are soft (core) plugs and a block drain plug. Some engines are equipped with plastic liners that direct coolant flow around critical areas. The soft plugs and drain plugs are usually removed during engine teardown. New ones are installed during reassembly. Core plugs are prone to rust and corrosion and, therefore, will weep coolant or rust through completely. When this happens, the core plugs should be replaced.

Hose Clamps

Hoses are attached to the engine and radiator with clamps (**Figure 14-29**). Hose clamps are designed to apply clamping pressure around the outside of the hose at the point where it connects to the inlet and outlet connections at the radiator, engine block, water pump, or heater core. The pressure exerted on this

Figure 14-28 The cooling system circulates coolant through the engine's water jackets.

Figure 14-29 Common types of hose clamps.

connection is important to making and maintaining a seal at that point.

Belt Drives

Belt drives are used to power the water pump and/or cooling fan on many engines. The belts must be in good condition and properly tensioned in order to drive this at the correct speed.

Chapter 7 for a detailed discussion of drive belts.

Heater System

A hot liquid passenger compartment heater is part of the engine's cooling system. Heated coolant flows from the engine through heater hoses and a heater control valve to a heater core located on either side of the fire wall (**Figure 14-30**). Air is directed or blown

Figure 14-30 The coolant for the heater core is sent from the upper part of the engine through the heater core and back to the inlet side of the water pump.

over the heater core, and the heated air flows into the passenger compartment. Movable doors can be controlled to blend cool air with heated air for more or less heat.

Cooling Fans

The efficiency of the cooling system depends on the amount of heat that can be removed from the system and transferred to the air. At highway speeds, the ram air through the radiator should be sufficient to maintain proper cooling. At low speeds and idle, the system needs additional air. This air is delivered by a fan (**Figure 14-31**). The fan may be driven by the engine,

Figure 14-31 A belt-driven cooling fan.

via a belt, or driven by an electric motor. A belt-driven fan is bolted to a pulley on the water pump and turns constantly with the engine. Thus, belt-driven fans always draw air through the radiator from the rear. The fan has several blades made of steel, nylon, or fiberglass, which are attached to a metal hub.

A fan that is placed more than 3 inches from the radiator is ineffective. It merely recirculates hot air around the fan blades. This is why most radiators are equipped with shrouds. A shroud is a large, circular piece of plastic, metal, or cardboardlike material that extends outward from the radiator to enclose the fan and increase its effectiveness. These shrouds should always be kept intact and not be modified.

Because fan air is usually only necessary at idle and low-speed operation, various design concepts are used to limit the fan's operation at higher speeds. Horsepower is required to turn the fan. Therefore, the operation of a cooling fan reduces the available horsepower to the drive wheels as well as the fuel economy of the vehicle. Fans are also very noisy at high speeds, adding to driver fatigue and total vehicle noise.

To eliminate this power drain during times when fan operation is not needed, many of today's belt-driven fans operate only when the engine and radiator heat up. This is accomplished by a **fan clutch** (Figure 14-32) located between the water pump pulley and the fan. When the engine and fan clutch are cold, the fan moves independently from the clutch and moves little air. The clutch locks the fan to its hub when the temperature of the air around the fan reaches a particular point. In most cases, the clutch slips at high speeds; therefore, it is not turning at full engine speed. The clutch assemblies rely on a thermostatic spring or silicone fluid.

Some engines have flexible blades or **flex-blades** that bend or change pitch based on engine speed. That

Figure 14-32 A viscous-type fan clutch.

Figure 14-33 This car has two separate electric cooling fans.

is, at slower speeds the blade pitch is at the maximum. As engine speed increases, the blade pitch decreases as does the horsepower losses and noise levels.

Electric Cooling Fans In most late-model applications, to save power and reduce the noise level, the conventional belt-driven, water pump-mounted engine cooling fan has been replaced with an electrically driven fan (Figure 14-33). This fan and motor are mounted to a shroud. The 12-volt, motor-driven fan is electrically controlled by an engine coolant temperature switch and/or the air conditioner switch.

As the schematic in Figure 14-34 shows, the cooling fan motor is connected to the battery through a normally open (NO) set of contacts in the cooling fan relay.

Figure 14-34 A simple schematic for an electric cooling fan.

Figure 14-35 A simple graph showing when an electric cooling fan turns on and off.

During normal operation, with the air conditioner off and the engine coolant below a predetermined temperature of approximately 215°F (101.6°C), the relay contacts are open and the fan motor does not operate.

When coolant temperatures exceed approximately 230°F (110°C), the coolant temperature switch closes (**Figure 14-35**). This energizes the fan relay coil, which in turn closes the relay contacts. The contacts provide 12 volts to the fan motor. When the air conditioner select switch is set to any cool position, regardless of engine temperature, a circuit is completed through the relay coil to ground. This closes the relay contacts to provide 12 volts to the fan motor. The fan then operates as long as the air conditioner and ignition switches are on.

There are many types of electric cooling fans. Some provide a cool-down period, which means the fan continues to run after the engine has been stopped and the ignition switch is turned off. These systems have a second temperature sensor. The fan stops only when the engine coolant falls to a predetermined temperature, usually about 210°F (98.8°C). In some systems, the fan does not start when the air conditioner is turned on unless the high side of the A/C system is above a predetermined temperature and/or pressure.

Some late-model cars control the cooling fan by completing the ground through the engine control computer. Check the service manual to see how an electric cooling fan is controlled before working with it.

CAUTION!

The electric cooling fan can come on at any time without warning even if the engine is not running. Always remove the negative terminal at the battery or the connector at the cooling fan motor while working around an electric fan. Make sure you reconnect the connector before giving the car back to the customer.

Figure 14-36 A coolant temperature sensor.

Temperature Sensors Proper electric cooling fan operation depends on the operation of a temperature sensor. A temperature sensor responds to changes in temperature. Some vehicles use more than one sensor to control the fans and to send engine temperature readings to the PCM. Based on this information, the PCM will adjust the fuel injection and ignition systems to provide efficient engine operation.

Temperature Indicators

Coolant temperature indicators alert the driver of an overheating condition. These indicators are a temperature gauge and/or a warning light. A temperature sensor is threaded into a bore in a water jacket (**Figure 14-36**). Besides displaying coolant temperatures, temperature sensors supply some important information to the computers in engine control systems.

COOLING SYSTEM DIAGNOSIS

The cooling system must be inspected and serviced as a system. Replacing one damaged part while leaving others dirty or clogged will not increase system efficiency. Diagnosis of the system involves both a visual inspection of the parts, simple checks and tests, and leak testing. One of the first checks of the cooling system is the checking of coolant level and condition. These checks should be done during normal preventive maintenance and when there is a problem. All diagnosis of the cooling system should begin with a check of the coolant.

Chapter 7 for a general discussion of checking the coolant level and condition.

There are marks on most expansion tanks that show where coolant levels should be when the car is hot and when it is cold. To check coolant levels on a car without a recovery tank, remove the radiator cap (when the engine is cold) and see if the coolant is up to where it should be. If there are no markings, make sure the coolant is covering the radiator core. If the coolant level is low after repeated filling, there is probably a leak in the cooling system. The condition or effectiveness of the coolant should be checked with a hydrometer, a refractometer, or alkaline test strips.

CAUTION!

When working on the cooling system, remember that at operating temperature the coolant is extremely hot. Touching the coolant or spilling it can cause serious body burns. Never remove the radiator cap when the engine is hot.

The proper mixture of water and antifreeze also reduces the amount of rust and lime deposits that can form in the system. These deposits tend to insulate the walls of the water jackets. As a result, the coolant is less able to absorb the engine's heat at the points where there is scale. This causes engine hot spots that result in increased component wear and make overheating more likely (**Figure 14-37**).

Regardless of the mixture of the coolant or the type of antifreeze used, some lime, rust, and scale will always build in a cooling system. Any deposit on the

Figure 14-37 Lime and dirt buildup in the coolant passages tend to insulate the walls of the water jackets and can cause hot spots that result in increased wear and make overheating more likely.

walls of the water jackets will affect engine cooling. Changes in engine temperature cause the engine parts to expand and contract. Some of these deposits then break off and become suspended in the coolant. The coolant then becomes contaminated and the deposits may collect at a narrow passage, making the passage narrower. This restriction would further lessen the effectiveness of the cooling system. For these reasons and others, the engine's coolant should be replaced and the cooling system flushed every 1 or 2 years.

Testing for Electrolysis in Cooling Systems

Electrolysis is a process in which an electrical current is passed through water, causing the separation of hydrogen and oxygen molecules. In a cooling system, electrolysis removes the protective layer on the inside of the radiator tubes. It also can cause serious engine failures. Electrolysis occurs when there is improper grounding of electrical accessories and equipment or static electricity buildup somewhere in the vehicle. Checking for these should be a part of all checks of the coolant.

To check for the conditions prone to electrolysis, use a voltmeter that is capable of measuring AC and DC voltage. Set the meter so it can read in tenths of a volt DC. Attach the negative meter lead to a good ground. Place the positive lead into the coolant (**Figure 14-38**). Look at the meter while the

Figure 14-38 The setup for checking for conditions that can cause electrolysis.

engine is cranked with the starter and record the readings. Take another reading with the engine running and all accessories turned on. Record that reading. Voltage readings of 0 to 0.3 volt are normal for a cast-iron engine; normal readings for a bimetal or aluminum engine are half that amount. Repeat the test with the DMM in the AC voltage mode. There will be AC voltage if the problem is static electricity. Any readings above the normal indicate a problem.

To isolate the problem, look at where the high voltage was measured and think about the systems that were energized during that time. If the voltage was high when all of the accessories were turned on, turn them off one at a time until the voltage drops to normal. The circuit that was turned off prior to the drop in voltage has ground problems. After the electrical problems have been corrected, flush and replace the coolant.

INSPECTION OF COOLING SYSTEM

The most common cooling system problem is overheating. There are many reasons for this. Diagnosis of this condition involves many steps, simply because many things can cause this problem (**Figure 14-39**). Basically, overheating can be caused by anything that decreases the cooling system's ability to absorb, transport, and dissipate heat: The first step is to determine whether the engine is indeed overheating.

SHOP TALK

A few late-model engines, such as GM's Northstar engine, will shut off cylinders to "air-cool" the engine and keep it running at reduced power when they overheat. This prevents the serious damage that may occur in other engines.

An overheating concern normally begins with high readings on the vehicle's temperature gauge or the illumination of the temperature warning lamp. These can be caused by a cooling system problem or a faulty temperature sensor, although when the engine is greatly overheating, it is obvious by the steam emitted by the system or by smell. The best way to check the accuracy of the temperature indicators is to measure the temperature of the coolant. If the indicators seem to be wrong, troubleshoot and repair the electrical circuit. Then recheck the system's temperature.

Condition	Cause
Overheats in heavy traffic or after idling for a long time	<ul style="list-style-type: none"> ■ Low coolant level ■ Faulty radiator cap ■ Faulty thermostat ■ Cooling fan is not turning on ■ Restricted airflow through the radiator ■ Leaking head gasket ■ Restricted exhaust ■ Water pump impeller is corroded

Figure 14-39 Common causes of engine overheating.

SHOP TALK

It is difficult to measure the actual temperature of the coolant on most late-model engines because the only access to the coolant is through the expansion tank. The coolant in the tank does not represent the coolant in the engine and it is not heated. Use a temperature probe or infrared sensor to measure the temperature of the inlet radiator tank. This will give an accurate measurement of system temperature.

Normal operating temperature for most engines is 195 to 220°F (91 to 104°C). To maintain this temperature, the coolant must circulate through the engine and radiator. Anything that will interfere with the movement of coolant, such as a faulty water pump or thermostat, or a loss of coolant, will cause overheating. Likewise anything that interferes with the passing of air through the radiator will also cause the engine to overheat.

Effects of Overheating

Engine overheating can cause the following problems:

- Detonation
- Preignition
- Blown head gasket
- Warped cylinder head
- OHC cam seizure and breakage
- Blown hoses
- Radiator leaks
- Cylinder damage due to swelling pistons
- Sticky exhaust valve stems
- Engine bearing damage

Temperature Test

A temperature test can be performed with an infrared temperature sensor, thermometer, or temperature probe. The latter may be a feature of a digital multimeter (DMM). A temperature test allows for monitoring temperature change through the cooling system. When a cold engine is started, the opening temperature of the thermostat can be observed as the engine warms. This can be compared to specifications to determine if the thermostat is bad. Once the engine has warmed up, the probe can be used to scan for cool spots in the radiator. These indicate an area where coolant is not flowing freely through the radiator. The cooling fan temperature switch can also be checked.

Radiator Checks

Cold spots on the radiator indicate internal restrictions. In most cases, this requires removal of the radiator so it can be deeply flushed or replaced. Normal cooling system flushing will normally not remove the restrictions. The restrictions are typically caused by internal corrosion or a buildup of scale and lime.

The radiator should also be inspected for external restrictions and for evidence of leaks. Dirt, bugs, and other debris on the surface of the radiator will block airflow. These should be removed by careful cleaning. Also, check for loose cooling fins. Salt and other road debris can corrode the solder used to attach the fins around the radiator's tubes. When the fins are not attached to the tubes, heat is not as easily transferred to the outside air.

Checking Hoses

Carefully check all cooling hoses for leakage, swelling, and chafing. Also replace any hose that feels mushy or extremely brittle when squeezed firmly (**Figure 14-40**). When a hose becomes soft, it is deteriorating and should be replaced before more serious problems result. Hard hoses will resist flexing and may crack rather than bend and should be replaced.

Normally, hoses begin to deteriorate from the inside. Pieces of deteriorated hose will circulate through the system until they find a place to rest. This place is usually the radiator core, causing clogging. Deterioration can also cause leaks. Any external bulging or cracking of hoses is a definite sign of failure. When one hose fails, all of the others should be carefully inspected.

Figure 14-40 Defects in cooling hoses.

The upper radiator hose has the roughest service life of any hose in the cooling system. It must absorb more engine motion than any of the other hoses. It is exposed to the coolant at its hottest stage, and it is insulated by the hood during hot soak periods. These conditions make the upper hose the most likely to fail.

Check the firmness of the lower radiator hose to make sure that the internal reinforcement spring is in place and not damaged. Without this reinforcement, the hose can collapse under vacuum at high engine speeds and restrict coolant flow from the radiator to the engine.

Squeeze each hose and look for splits. These splits can burst wide open under pressure. Also look for rust stains around the clamps. Rust stains indicate a leak, possibly because the clamp has eaten into the hose. Loosen the clamp, slide it back, and check the hose for cuts.

A major cause of hose failure is an electrochemical attack on the rubber hose. This is known as **electrochemical degradation (ECD)**. It occurs because the hose, engine coolant, and the engine/radiator fittings form a galvanic (battery) cell. This chemical reaction causes very small cracks in the hose, allowing the coolant to attack and weaken the reinforcement in the hose (**Figure 14-41**). ECD can cause pinhole leaks or hose rupture under normal operating pressures. The effects of ECD are accelerated by high temperatures and vibrations.

The best way to check hoses for ECD is to squeeze the hose near the clamps or connectors. ECD occurs within 2 inches of the ends of the hose—not in the middle. Compare the feel of the hose between the middle and the ends. Gaps can be felt along the length

of the hose where it has been weakened by ECD. If the ends are soft and feel mushy, chances are the hose is under attack by ECD and the hose should be replaced.

Oil is another enemy to rubber hoses. A hose damaged by oil is swollen, soft, and sticky. If the oil leak is external, eliminate the oil leak or try to reroute the hose away from the oil leak to prevent oil damage to a new hose. At times, the oil damage occurs inside the hose. This can be caused by transmission fluid leaking into the coolant or an internal engine oil leak.

Belt Drives

Belts tend to overcure due to excessive heat. This causes the rubber to harden and crack. Excessive heat usually comes from slippage. Slippage can normally be attributed to lack of proper belt tension or oily conditions. When slippage occurs heat not only overcures the belt, it also travels through the drive pulley and down the shaft to the support bearings. These bearings might be damaged if the slippage is allowed to continue. As a V-belt wears, it begins to ride deeper in the pulley groove. This reduces its tension and promotes slippage. Carefully inspect all drive belts and replace them as necessary.

Chapter 7 for the correct procedure for changing a belt and adjusting its tension.

Figure 14-41 An ECD-damaged hose. *Courtesy of Gates Corporation*

Checking Fans and Fan Clutches

The cooling fan is a very important part of the cooling system. Most engine-driven fans have a clutch, and most overheating problems are caused by a defective clutch. However, the fan itself as well as the fan shroud must be thoroughly checked. The fan shroud should be securely fastened to the radiator bracket. The shroud should also be checked for cracks and other damage. A damaged shroud should be replaced.

Any damage or distortion to the fan will cause it to be out of balance. This can cause major problems, including rapid and excessive water pump bearing and seal wear or damage to the radiator if the fan blades hit the radiator. A noticeable wobble as the fan spins means that the fan should be replaced.

Fan clutches are filled with silicone oil. The oil responds to speed and temperature. As the engine increases speed, the oil allows the fan to slip on its hub. This reduces the drag on the engine. If the clutch allows the fan to slip during low engine speeds,

overheating can occur. A loss or deterioration of the oil will cause fan slippage. Over time, the oil begins to break down and offers less of a coupling between the fan and hub. It is said that the life of a fan clutch is about the same as that of a water pump and when one needs replacing, the other should also be replaced.

The clutch assembly should be carefully checked for leakage. Oily streaks radiating outward from the hub shaft mean that fluid has leaked out past the bearing seal. A leaking clutch should be replaced. The clutch should also be replaced if the fan can be spun with little or no resistance with the engine off, if the clutch wobbles when the fan is moved in or out, or if there are damaged or missing fins on the assembly.

Electric Cooling Fans The action of the electric cooling fan should be observed. However, before doing so, check the mounting of the fan assembly and the condition of the fan blades. The fan should be energized when the A/C is turned on and when the coolant reaches a specified temperature. If the fan does not turn on when it should, check the motor. Do this by connecting the motor directly to the battery. If the motor runs, the problem is in the motor's control circuit. Diagnosis of this problem should follow the prescribed sequence given by the manufacturer. If the jumped motor does not run, the problem is the fan motor (**Figure 14-42**).

Testing the Thermostat

Thermostats are often the cause of overheating or poor heater performance. They can also cause an increase in fuel consumption and poor engine performance.

Figure 14-42 Test each fan motor by connecting battery power to terminal 1 and a ground to terminal 2. If either motor fails to run or does not run smoothly, replace it.

Electronic engine control systems are programmed to deliver the ideal air-fuel mixture and ignition timing according to the engine's operating conditions. One of the conditions monitored by the PCM is engine temperature. The PCM also controls and regulates engine coolant temperatures to optimize efficiency.

A properly working thermostat is closed when the engine is cold and the coolant's temperature is lower than the thermostat's rating. Once the coolant reaches the opening temperature of the thermostat, the thermostat opens and allows coolant to flow to the radiator. The hotter the coolant gets, the more the thermostat opens, allowing more coolant to flow through the radiator. If the thermostat is stuck open, the coolant may not reach the desired temperature because it is cooled before it gets hot. If a thermostat is stuck closed because it failed or because there is a steam pocket below the thermostat, coolant will not flow between the engine and the radiator; the engine will, therefore, quickly overheat. The presence of steam results from low coolant levels or air in the system.

The easiest way to check thermostat operation is to measure engine temperature with an infrared thermometer (**Figure 14-43**). However, you can use your hand to feel the temperature. Touch the upper and lower radiator hoses when the engine is first started. If the hoses do not become hot within several minutes, the thermostat is not opening.

Another way to test a thermostat is to remove it and totally submerge it in a small container of water so that it does not touch the bottom (**Figure 14-44**). Place a thermometer in the water so that it does not touch the container and only measures water temperature. Heat the water. When the thermostat begins to open, read the thermometer. This is the

Figure 14-43 The operation of a thermostat can be observed with an infrared thermometer.

Figure 14-44 A thermostat can be tested by submerging it in water, heating the water, and observing the temperature at which the thermostat begins to open.

opening temperature of the thermostat. Then remove the thermostat from the water and allow it to cool. If the valve stays open after the thermostat is removed from the water, the thermostat is defective and must be replaced.

Water Pump Checks

Water pumps are driven by a belt, the crankshaft or camshaft, or by an electrical motor. A water pump pulls coolant from the radiator and pushes it through the engine. If the water pump is not working properly, the engine will quickly overheat. Seldom does a pump merely stop working. Problems with a pump are normally noise or leakage. An exception to this is electrically operated pumps. Electric problems can cause the pump to totally stop. The cause of these problems is identified by troubleshooting the circuit.

The majority of water pump failures are attributed to leaks. When the pump bearings and seals begin to fail, coolant will seep out of the weep hole in the casting or through the outer seal (**Figure 14-45**). The seals may be worn out due to age or abrasives in the system, or they may have cracked because of thermal shock, such as adding cold water to an overheated engine.

CAUTION!

As soon as a water pump begins to leak, it should be replaced. Not only will the leak get worse and cause serious overheating, there is also the chance of the pump's shaft breaking and the fan moving into and destroying the radiator.

Figure 14-45 This pump shows signs of bad leaks.

Other failures can be attributed to bearing and shaft problems and an occasional cracked casting. Water pump bearing or seal failure can be caused by surprisingly small out-of-balance conditions that are difficult to spot. Look for the following: a bent fan, a piece of the fan missing, a cracked fan blade, a dirty fan-mounting surface, and a worn fan clutch. Any wobble of the pump shaft or fan means the pump and/or fan should be replaced.

Through time, the impeller blades may corrode or come loose from the shaft. Both of these situations will cause the pump not to work and it must be replaced. In less extreme cases, corrosion may cause the impeller to be loose on the shaft and not rotate all of the time. This can cause an intermittent cooling problem. Unfortunately, the only sure way of knowing the condition of the impeller is to remove the pump and inspect it.

To check the operation of the water pump, start the engine and allow it to warm up. Squeeze the upper radiator hose (**Figure 14-46**) and accelerate the

Figure 14-46 The operation of the water pump can be checked by squeezing the upper radiator hose while accelerating the engine. If a surge is felt in the hose, the pump is working.

engine. If a surge is felt in the hose, the pump is working.

Air in the cooling system can prevent the pump from working properly. To check for the presence of air, attach one end of a small hose to the radiator overflow outlet and put the other end into a jar of water. Then make sure all hose connections are tight, and the coolant level is correct. Run the engine and bring it to its normal operating temperature. Then run the engine at a fast idle. If a steady stream of bubbles appears in the jar, air is getting into the system.

The air may be entering the system because of a bad head gasket. Conduct a combustion leak or compression test. If the results of the compression test show that two adjacent cylinders tested have low compression, the gasket is bad or there is an air leak somewhere else in the cooling system.

On belt-driven pumps, turn the engine off and remove the drive belt and shroud. Grasp the fan and attempt to move it in and out and up and down. More than $\frac{1}{16}$ inch (1.58 mm) of movement indicates worn bearings that require water pump replacement.

If the concern is excessive noise, start the engine and listen for a bad pump bearing, using a mechanic's stethoscope. Place the stethoscope on the bearing or pump shaft. If a louder-than-normal noise is heard, the bearing is defective.

CAUTION!

Whenever working near a running engine, keep your hands and clothing away from the moving fan, pulleys, and belts. Do not allow the stethoscope or rubber tubing to be caught by the moving parts.

TESTING FOR LEAKS

The most common cause of overheating is low coolant levels due to a leak. Leaks can occur anywhere in the system. The most common leak points include the hoses, radiator, heater core, water pump, thermostat housing, engine freeze plugs, transmission oil cooler, cylinder head(s), head gasket, and engine block. Often only a visual inspection of the cooling system and engine is necessary to find the source of a leak. The point of the leak may be wet or have a light gray color, the result of the coolant evaporating at that point.

Pressure Testing

A radiator pressure tester is the most common tool used to test a cooling system. It is extremely handy

for finding the source of any leak in the cooling system. The tester applies pressure to the entire cooling system. A good cooling system should be able to hold about 14 psi (93 kPa) for 15 minutes or more without losing pressure. The procedure for using a pressure tester is given in Photo Sequence 11.

To use the tester, connect it to the radiator filler neck. Run the engine until it is warm, then pump the handle of the tester until the gauge reads the same pressure noted on the radiator cap. Watch the gauge. If the pressure drops, carefully check the hoses, radiator, heater core, and water pump for leaks. Often the leak will initially be obvious because coolant will spray out of the leak. Also look for bulges in the hoses. These indicate that the hose is soft and weak and should be replaced. If the pressure drops but there are no external leaks, suspect an internal leak. The source of internal leaks is found through additional testing.

An internal leak caused by a bad head gasket can be verified with the pressure tester. Relieve all pressure in the cooling system. Install the pressure tester onto the radiator filler neck and start the engine. Allow the engine to idle and watch the gauge on the tester. If the pressure begins to build, it is more than likely that the head gasket is blown and combustion gases are entering the coolant.

Leak Detection with Dye Another common way to identify the source of an external leak is to use dye penetrant and a black light. The dye is poured into the cooling system and the engine run until it reaches operating temperature. With the engine off, the engine and cooling system are inspected with the black light. Where the dyed coolant leaks, a bright or fluorescent green color will be seen (**Figure 14-47**).

Figure 14-47 A common way to identify the source of an external leak is to use dye penetrant and a black light. Where the dyed coolant leaks, a bright or fluorescent green color will be seen. *Courtesy of Tracer Products*

P11-1 Remove the radiator cap.

P11-2 Top off the coolant level.

P11-3 Connect the tester to the radiator's filler tube and apply pressure to the system by pumping the handle of the tester.

P11-4 Once the pressure is equal to the rating of the pressure cap, watch for a pressure decrease and look for leaks.

Using a Cooling System Pressure Tester (*continued*)

P11-5 Using the appropriate adapter, mount the pressure cap to the tester.

P11-6 Apply pressure to the cap that is equal to the cap's rating. If the cap does not hold that pressure, replace it. Then apply more pressure. If the cap is good, the excess pressure will vent through the cap.

P11-7 Correct any leaks and top off the fluid level.

Figure 14-48 A combustion leak tester.

Combustion Leak Check Internal leaks are suspected when there are no visible external leaks but the engine is losing coolant or could not hold pressure during the pressure test. These leaks are typically caused by a cracked cylinder head or block or a bad head gasket that is allowing coolant to leak into the cylinders or combustion gases leak into the cooling system. Sometimes steam, white smoke, or water in the exhaust, or coolant in the oil or oil in the coolant, will give a hint that there is a bad head gasket.

A combustion leak tester (**Figure 14-48**) is used to determine whether combustion gases are entering the cooling system. This tester is basically a glass tube with a rubber bulb. The tube is fit with a one-way valve at the bottom. To check for combustion gas leaks, follow this procedure:

PROCEDURE

1. Start the engine and allow it to reach normal operating temperature.
2. Fill the tester's glass tube with the test fluid (normally a blue liquid).

3. Carefully remove the radiator cap.
4. Make sure the coolant level in the radiator is below the lower sealing area of the filler neck.
5. Place the tester's tube into the filler neck.
6. Rapidly squeeze and release the rubber bulb. This will force air from the radiator up through the test fluid.
7. Observe the liquid. Combustion gases will change the color of the liquid to yellow. If the liquid remains blue, combustion gases were not present.
8. Dispose of the test fluid; never return used test fluid to its original container.

A bad head gasket normally results from another problem. Make sure that problem is corrected before replacing the gasket. Bad head gaskets should be replaced as soon as possible. The excessive heat and pressures resulting from this problem are far greater than what a cooling system can handle and can lead to serious engine problems.

SHOP TALK

The O₂ sensor should be replaced after a head gasket is replaced or if there was a crack in the head or block. Coolant contains silicone and silicates that may contaminate the sensor.

Testing the Radiator Pressure Cap

The opening pressure of the radiator cap should be measured and the cap checked for gasket cracking, brittleness, or deterioration (**Figure 14-49**). Over time the spring in the cap can weaken and will lower the coolant's boiling point. This will cause the engine to lose coolant through the overflow tube whenever it gets hot. Also check the sealing surfaces in the radiator filler neck.

Install the correct cap adapter and radiator pressure cap to the tester head. Pump the tester until the gauge reads the pressure rating of the cap. The cap should hold that pressure for at least 1 minute. If it does not, replace it. Apply a pressure greater than the cap's rating. A good cap will vent the excess pressure. Remove the cap from the tester and visually inspect the condition of the cap's pressure valve and upper and lower sealing gaskets. If the gaskets are hard, brittle, or deteriorated, the cap may leak when exposed to hot, pressurized coolant. It should be replaced with a new cap in the same pressure range.

Figure 14-49 Radiator cap inspection. Courtesy of Ford Motor Company

WARNING!

The radiator cap should never be removed when the radiator is hot to the touch. When the pressure in the radiator is suddenly released, the coolant's boiling temperature is reduced. This causes the coolant to immediately boil. Because coolant is a thick liquid, it will stick to your skin and can cause severe burns. The radiator should be allowed to cool, or you can force cool it by lightly spraying water on the radiator. When the cap is cool and the engine is shut off, use a cloth over the cap and turn it counterclockwise one-quarter turn to its safety stop and release the pressure. Let the cap remain in this position until all pressure subsides. When all discharge ends, use a cloth over the cap, press it down, and turn it counterclockwise to remove the cap.

Water Outlet

Internal corrosion, contributes the failure of water outlets. Cast-iron water outlets are more resistant to corrosion than stamped steel or cast aluminum outlets. A more common cause of failure for a water out-

let is the uneven torquing down of the mounting bolts, which can cause a mounting ear to break off. When this happens, the outlet will not seal and must be replaced.

COOLING SYSTEM SERVICE

Service to the cooling system entails replacing leaking or broken parts as well as emptying, flushing, and refilling the system. One of the common services is replacing the drive belt. Belts are a common wear item and should be installed at the correct tension. A loose belt will slip and prevent the water pump from moving coolant fast enough through the engine and/or turn the fan fast enough to cool the coolant.

The water pump on many late-model engines is driven by the engine's timing belt or chain. When replacing the water pump on these engines, always replace the timing belt. Make sure all pulleys and gears are aligned according to specifications when installing the belt.

Chapter 7 for a detailed discussion of drive belts and the correct procedure for changing a belt and adjusting its tension.

Hoses

Customer Care

Technicians should do their customers a favor and remind them that all cooling hoses should be replaced every 2 to 4 years to prevent breakdowns.

Replacement hoses must be made of the right material and have the correct diameter, length, and shape. The hose's part number is often printed on the outside of the hose and replacement hoses should match or correspond to those numbers (**Figure 14-50**).

Nearly all OEM hoses are of the molded, curved design. Lower radiator hoses are normally wire reinforced to prevent collapse due to the suction of the water pump. Molded hoses designed to fit many applications are often sold. The hose is cut to fit a specific application. Some have printed cutoff marks on them to show where they should be cut. Others should be compared to the old hose for a cut reference.

Figure 14-50 Nearly all radiator hoses have a part number painted on the outside of the hose. These should be used when replacing a hose.

Figure 14-51 Aftermarket replacement hoses are either molded (top) or flex types (bottom).

Aftermarket hoses are either molded or flex types (**Figure 14-51**). A flex-type hose allows greater vehicle coverage per part number. Flex hoses are available in different lengths and diameters. They can flex or bend into most required shapes without causing a restriction. Flex hoses may not be desirable for some systems that require radical bends and shapes.

Rather than replacing heater hoses with the molded type, formable heater hoses are available. This hose design has a wire spine. The wire spine allows the hose to bend into a curve without collapsing at the bend. Once the desired shape is obtained, the hose is cut to length and then installed.

All cooling system hoses are basically installed the same way. The hose is clamped onto inlet-outlet nipples on the radiator, water pump, and heater.

When replacing a hose, drain the coolant system below the level that is being worked on. Loosen or carefully cut the old clamp. With a knife, carefully cut the end of the old hose (**Figure 14-52**) so it can slide

Figure 14-52 Cutting off an old hose.

Figure 14-53 New clamps should be placed immediately after the bead of the fitting.

off its fitting. If the hose is stuck, do not pry it off. You could possibly damage the inlet/outlet nipple or the attachment between the end of the hose and the bead. Simply make more cuts into the hose.

Always clean the neck of the hose fitting or nipple with a wire brush or emery cloth after the old hose has been removed. Burrs or sharp edges can cut the hose and lead to premature failure. Dirty connections will prevent a good seal.

Dip the ends of the hose in coolant and slip the clamps over each end. Do not reuse spring-type clamps, even if they look good. Slip the hose over its fittings, engine end first. In cold weather, the hose may be stiff; it can be soaked in warm water to make it more flexible. If the hose does not fit properly, remove it and reverse the ends. Then slide the clamps to about $\frac{1}{4}$ inch from the end of the hose after it is properly positioned on the fitting (**Figure 14-53**). Tighten the clamp securely but do not overtighten.

Hose Clamps Original equipment clamps are usually spring steel wires that are removed and replaced with special pliers. A worm drive hose clamp is often used as a replacement for many reasons. It provides even pressure around the outside of the hose. It is also easy to install and requires no special tools.

Rather than using steel clamps, some technicians prefer to use thermoplastic clamps (**Figure 14-54**). These heat-sensitive clamps are installed on the hose ends and a heat gun is used to shrink the clamp. The shrinking of the clamp tightens the connection. As the engine runs, the heat of the coolant further tightens the connection.

Figure 14-54 Thermoplastic clamps are tightened with a heat gun. *Courtesy of Gates Corporation*

It is a good idea to readjust the clamp of a newly installed hose after a brief run-in period. The hose does not contract and expand at the same rate as the metal of the inlet/outlet nipple. Rubber hoses, warmed by the hot coolant and hot engine, will expand. When the engine cools, the fitting contracts more than the rubber, and the hose will not be as secure. This can result in cold coolant leaks at the inlet/outlet nipple. Retightening the clamp eliminates the problem.

Thermostat

When replacing the thermostat, the replacement should always have the same temperature rating as the original. Since 1971, nearly all engines require a thermostat with 192° or 195° ratings. Using a thermostat with a different opening temperature than was originally installed on a computerized engine will affect the operation of the fuel, ignition, and emissions control systems. This is due to the fact that the wrong thermostat can prevent the system from going into closed loop.

Replacement Markings on the thermostat normally indicate which end should face toward the radiator. Regardless of the markings, the sensed end must always be installed toward the engine.

When replacing the thermostat, also replace the gasket that seals the thermostat in place and is positioned between the thermostat housing and the block. Make sure the mating surfaces on the housing

Figure 14-55 Make sure all old gasket material is removed before installing a new thermostat gasket and housing.

Figure 14-56 Some thermostat housings are sealed with a liquid gasket.

and block are clean and free of old gasket material (**Figure 14-55**). Some housings are sealed with a liquid gasket (**Figure 14-56**). A thin line of the liquid gasket should be applied around the water passages, and the housing installed before the liquid dries.

Normally there are locating pins on the thermostat that are used to position the thermostat in the block and housing (**Figure 14-57**). Most thermostats and housings are sealed with gaskets or rubber seals. The gaskets are normally composition fiber material cut to match the thermostat opening and mounting bolt configuration of the housing. Thermostat gaskets generally come with an adhesive backing. The backing holds the thermostat securely centered in the mounting flange. This makes it easier to properly align the housing to the block.

Repairing Radiators

SHOP TALK

Always refer to application charts or a service manual when replacing a pressure cap to make sure that the new cap has the same pressure range as the original cap.

Figure 14-57 Normally there are locating pins on the thermostat that are used to position the thermostat in the block and housing.

Most radiator leak repairs require the removal of the radiator. Coolant must be drained and all hoses and oil cooler lines disconnected. Bolts holding the cooling fans and radiator are then loosened and removed.

The actual radiator repair procedures depend on its construction and the type of damage. Most repairs are made by radiator specialty shops whose technicians have knowledge of such work. Many of today's radiators have plastic tanks, which are not repaired. If these tanks leak, they are replaced. If the radiator is badly damaged, it should be replaced.

CAUTION!

When working on the coolant system, for example, replacing the radiator, thermostat, or water pump, a certain amount of coolant will spill on the floor. The antifreeze in the coolant causes it to be very slippery. Always immediately wipe up any coolant that spills to reduce or eliminate the chance of injury.

Replacing the Water Pump

When replacing a water pump, make sure that the replacement is the correct one. Using the wrong pump can cause engine overheating.

The water pump on some engines with a serpentine belt turns in the opposite direction to that used on the same engine with a V-belt.

Figure 14-58 Installing a water pump.

Before replacing a water pump, the cooling system should be drained. Remove all parts that will interfere with the removal of the pump. This includes the drive belts, fan, fan clutch, fan shroud, and pump pulley. Most pumps are bolted to the block as shown in **Figure 14-58**.

Loosen and remove the bolts in a crisscross pattern from the center outward. Insert a rag into the block opening and scrape off any remains of the old gasket. When replacing a water pump, always follow the procedures given by the manufacturer. Most often a coating of adhesive should be applied to a new gasket before it is placed into position on the water pump. Some pumps are sealed to the block with an O-ring. Make sure that

the O-ring groove in the block is clean. When installing the O-ring, make sure it is totally inserted in the groove. Lubricate the O-ring to ensure it will not tear during installation. Position the pump against the block until it is properly seated. Install the mounting bolts and tighten them evenly in a staggered sequence to the torque specifications. Careless tightening can cause the pump housing to crack. Check the pump to make sure it rotates freely.

The water pumps on many late-model OHC engines are driven by the engine's timing belt. When replacing the water pump on these engines, always replace the timing belt. Make sure all pulleys and gears are aligned according to specifications when installing the belt.

Draining the Coolant

An important part of a preventive maintenance program is changing the engine's coolant. This is done to prevent the coolant from breaking down chemically. When this happens, the coolant becomes too acidic. This should be done every 2 to 4 years. Obviously, draining the coolant is the first step in doing this. The coolant should also be drained when replacing cooling system parts.

Before draining the coolant, find the capacity of the system in the vehicle's specifications. This allows you to know what percentage of the coolant has been drained. Normally, 30% to 50% of the coolant will remain in the system.

Most radiators have a drain plug located in the lower part of a tank. Some have a petcock valve. Make sure the engine is cool before draining the coolant. Set the heater controls to the HOT position. Remove the radiator pressure cap. Remove the overflow reservoir and empty it into a catch can. Now, place the catch can under the drain plug and remove the plug. If the radiator has a petcock, open it fully. If the radiator does not have a drain plug, remove the lower radiator hose. Be careful not to force the hose away from the radiator. The tube on the radiator can be easily broken by excessive force. Twist the hose back and forth while pulling it off. If the hose is stuck, slip a thin screwdriver between the hose and the radiator tube to loosen it. After the coolant stops flowing out, install the drain plug or close the petcock.

Additional coolant can be drained through drain plugs in the engine block (**Figure 14-59**). Place the catch can below the drain plug and remove the plug. Once the coolant has drained, replace the plug. Make sure to apply sealer on the threads of the plug. Clean up any spilled coolant.

Figure 14-59 Most engines have drain plugs that allow for draining coolant out of the block.

CAUTION!

Never pour engine coolant into a sewer or onto the ground. Used coolant is a hazardous waste and its disposal should be in accordance to local laws and regulations.

CAUTION!

Coolant can be very dangerous to children and animals. It has a sweet taste and can be deadly if ingested. Never keep coolant in an open container.

Coolant Recovery and Recycle System Whenever coolant is drained to service the cooling system, the used coolant should be drained and recycled by a coolant recovery and recycle machine. Typically additives are mixed into the used coolant during recycling. These additives either bind to contaminants in the coolant so they can be easily removed, or they restore some of the chemical properties in the coolant.

Flushing Cooling Systems

Whenever coolant is changed—and especially before a water pump is replaced—a thorough flushing should be performed. The bottom of the radiator will trap rust, dirt, and metal shavings. Draining the system will only remove the contaminants that are suspended in the drained fluid. Rust and scale will inevitably form in any cooling system. Buildups of these will affect the efficiency of the cooling system and can cause blockages inside the radiator. Flushing may not remove all debris. In fact if the radiator

REVERSE FLUSHING RADIATOR

Figure 14-60 The typical setup for back flushing a cooling system.

is plugged, the radiator should be removed and rebuilt or it should be replaced.

The system can be flushed in many ways. Power flushing equipment is often used to force the old coolant and contaminants out of the system. This function is often part of the operating cycle of a coolant exchanger. Back flushing forces clean water backward through the cooling system. The discharge of fluid carries away rust, scale, corrosion, and other contaminants. Flushing guns use compressed air to back flush the system and to break loose layers of dirt and other debris (**Figure 14-60**). This method of flushing the system is not recommended on systems that use plastic and aluminum radiators. Check the service manual for the proper way of cleaning out the cooling system in the vehicle being serviced.

A simple way to flush the system is to drain it and fill it with water. The engine is then run and brought to its operating temperature. At this point the engine is shut down and allowed to cool. The coolant is then drained. These steps are repeated until the discharged fluid is clear. The clear fluid indicates that all of the old coolant has been removed. Once this occurs, the system is drained again and refilled with coolant.

Flushing Chemicals Many different flush chemicals are available. Before using any chemical, make sure it is safe for the type of radiator. Coolant exchangers often use chemicals as part of their flushing function. The typical procedure for using flushing chemicals is to drain the system. Then pour the chemical into the radiator and top off the radiator with water. Install

Figure 14-61 Stop leak being added to the cooling system. Courtesy of Honeywell International Inc.

and tighten the radiator cap. Now start the car and set the heater control to its hottest position. Allow the engine to run until it reaches normal operating temperature. Then turn the engine off and allow it to cool. Once the engine has cooled, completely drain the radiator. If the flushing chemical requires a neutralizer, add it to the water remaining in the system and then refill the system with fresh coolant.

Customer Care

Many additives, inhibitors, and quick-fix remedies are available for cooling systems. These include, but are not limited to, stop leak, water pump lubricant, engine flush, and acid neutralizers. Stop leak or sealers (**Figure 14-61**) are often used to plug small leaks in the cooling system. These chemicals work to seal leaks in the radiator and engine (metal components). They do not seal leaking hoses and hose connections. Explain to your customers that caution should be exercised when using any additive. They must make sure that the chemicals are compatible with their cooling system. For example, caustic solutions must never be used in aluminum radiators. Alcohol-based remedies should never be used in any cooling system.

Refilling and Bleeding

After the cooling system has been drained and all services performed, the system needs to be refilled with the proper type and mixture of coolant. It is important that the correct type is put into the system. The color of the coolant normally indicates its purpose: Most coolants are green, extended-service coolants are orange, and special Toyota coolants are red. The additives in

orange coolant are not chemically compatible with those in green or red coolant; therefore, the system must be completely drained and flushed before switching from orange to red or green, or vice versa.

When refilling a system, determine the total capacity of the system. Half of the capacity is the amount of undiluted coolant that should be put into the system. Then top off the system with water. Loosely install the radiator cap. Run the engine until it reaches operating temperature. Then turn it off and correct the level of the coolant. Tighten the radiator cap and run the engine again and check for leaks.

When refilling the cooling system, be sure you get it completely full. Some systems are difficult to fill without trapping air. Air pockets in the head(s), heater core, and below the thermostat can prevent proper coolant flow and cooling. If air is trapped in the engine block or cylinder head(s), it can also cause “hot spots.” This can ruin the head gaskets, the cylinder walls, and the entire cooling system.

This is more of a problem on newer vehicles than older ones. In older cars, the top of the radiator sat higher than the rest of the cooling system. This positioning allowed air in the system to escape through the radiator cap. The radiator cap on many newer cars is much lower than the rest of the cooling system. This results from the lower hood lines. Because all liquids seek a natural level, that level may be above the cap and air gets trapped easily in other high places such as the block or head(s).

These new vehicles must be purged of the air after refilling. This can be done in many ways. Sometimes jacking up the front of the car will raise the radiator cap higher than the rest of the cooling system. With the radiator cap in its first lock position, start the engine. Allow it to run until the thermostat opens and the coolant circulates. Trapped air bubbles will naturally blow out the cap. When no more air escapes, shut off the engine and correct the coolant level. Then reinstall the radiator cap and tighten it to its fully locked position.

When refilling a system on a late-model vehicle, always check the service information for the correct coolant fill procedure. Each vehicle may have its own specific bleeding procedure. Some engines have air bleed valves located at the high point in the system (**Figure 14-62**). Check the service manual for their location. These valves allow air to escape while the system is being filled.

To use the air bleeds, make sure the engine is warm and the heater is fully on. Connect a hose to the end of the valves and place the open end in a catch can. Open all bleed valves. Slowly put the required amount of coolant into the radiator until the coolant

Figure 14-62 Some cooling systems are equipped with air bleed screws.

begins to leak out of the valves. Then close the valves and top off the system.

If the system does not have a bleeder valve, disconnect a heater hose at the highest point in the system. Once fluid flows steadily out of the hose, reconnect the hose. If the system was previously fit with a flushing Tee, remove its cap to purge the system. Always recheck the fluid level and make sure that all air is purged before putting the car back into service.

Special Precautions for Hybrid Vehicles

Special coolants are required in most hybrids because the coolant cools the engine and the converter/inverter assembly. Cooling the converter/inverter is important, and checking its coolant condition and level is an additional check during preventive maintenance. The cooling systems used in some hybrids feature electric pumps and storage tanks. The tanks store heated coolant and can cause injury if the technician is not aware of how to carefully check them.

Toyota hybrids have a system that heats a cold engine with retained hot coolant to provide reduced emissions levels. Hot coolant is stored in a container (**Figure 14-63**). The coolant will circulate through the engine immediately after startup. The fluid also may circulate through the engine many hours after it is shut off. This fluid is under pressure and can cause serious burns to anyone who opens the system for inspection and/or repairs. To safely service this cooling system, the pump for the storage tank must be disconnected. The cooling system also is tied into the converter/inverter assembly. This also presents a potential problem, because it is easy to trap air in the cooling system due to the path of coolant flow (**Figure 14-64**). To purge the system of air, there is a bleeder screw, and a scan tool is used to run the electrical water pump.

Figure 14-63 Toyota hybrids have a hot coolant storage container.

CAUTION!

The coolant in the coolant heat storage tank may be hot when the engine and radiator are cold. Also, never remove the radiator cap when the engine or radiator is hot.

PROCEDURE

The recommended procedure for draining and refilling the cooling system on a Toyota hybrid includes the following steps.

1. Remove the radiator's top cover and cap.
2. Disconnect the electrical connector on the water pump to prevent circulation of the coolant.

3. Connect a drain hose to the drain port on the bottom of the coolant heat storage tank, and then loosen the yellow drain plug on the tank.
4. Connect a drain hose to the drain port on the lower left corner of the radiator, and then loosen the yellow drain plug on the radiator.
5. Connect a drain hose to the drain port on the rear of the engine and loosen the drain plug.
6. After the coolant is drained, tighten the three drain plugs.
7. Reconnect the connector to the coolant heat storage tank's water pump.
8. Connect a hose to the radiator's bleeder valve port and place the other end of the hose into the coolant reservoir tank.
9. Loosen the radiator's bleeder plug.
10. Fill the radiator with the correct coolant.
11. Tighten the radiator's bleeder plug and install the radiator cap.
12. Connect the scan tool to DLC3.
13. Using the scan tool, run the water pump for the storage tank for 30 seconds.
14. Then loosen the radiator's bleeder plug.
15. Remove the radiator cap and top off the coolant in the radiator.
16. Repeat the refilling and bleeding sequence as often as necessary. Normally when no additional coolant is needed after the sequence, the system is bled.
17. Start the engine and allow it run for 1 to 2 minutes.
18. Turn off the engine and top off the fluid, if necessary.

Ford hybrids have two separate cooling systems: One is for engine cooling and the other is for hybrid components, called the Motor Electronics (M/E) cooling system. The engine cooling system is

Figure 14-64 Since the reservoir tank and inverter is higher than the radiator cap, air is easily trapped during coolant refilling.

Figure 14-65 The electric water pump for the M/E cooling system on a Ford Escape Hybrid.

conventional. The M/E cooling system uses an electric water pump (**Figure 14-65**) to move coolant through the inverter, transmission, and a separate radiator mounted next to the conventional radiator (**Figure 14-66**). The M/E coolant reservoir is located behind the engine coolant reservoir. Although the two systems operate similarly, the M/E cooling system typically operates at lower pressures and

temperatures. The fluid levels in both cooling systems must be maintained.

It is easy to trap air in the M/E cooling system when filling the system. The system is fitted with a bleeder screw at the top of the inverter (**Figure 14-67**). When servicing the system, make sure the high-voltage system is isolated by having the service connector in the **SERVICING/SHIPPING** position. Also, wear lineman's gloves because the bleeder screw is very close to the high-voltage cables.

Coolant Exchangers

A coolant exchanger (**Figure 14-68**) is used to remove old coolant from the system and to put in new coolant at the correct mixture. Some coolant exchangers will also leak test the system and flush it. Coolant exchangers are normally powered by shop air, although a few are powered by the vehicle's battery. Most exchangers move through their cycles with the engine off.

Figure 14-66 The radiator assembly for a Ford Escape Hybrid.

Figure 14-67 Location of the cooling system bleeder screw on a Ford Escape Hybrid.

Figure 14-68 A coolant exchanger. Courtesy of RTI Technologies, Inc.

The machine is connected to the radiator filler neck, upper radiator hose, or a heater hose. The old coolant is siphoned out of the system and stored in a container. When all coolant is out, the low pressure in the cooling system siphons the fresh coolant mixture out of another container. The entire process, including flushing the system, takes only a few minutes. When complete, the system is free of air and full of coolant.

CASE STUDY

A late-model minivan's engine overheats while going up a mountain road. It is a very hot day so water is added to the radiator and the trip continues. After driving 30 miles, the engine overheats again. Again water is added. The engine is allowed to cool for an hour while the owner eats. After about 30 miles of driving, the engine overheats again. This time the van is taken to a service station to be diagnosed and repaired. It is late in the day and the owner agrees to stay overnight at a local motel. A fresh supply of water is added to the radiator and the owner drives about a mile to the motel.

In the morning the owner adds water to the system. The van is brought back to the service station for diagnosis. It is obvious that the engine is overheating and there is a loss of fluid. There is no need to verify the customer's complaint. A visual inspection shows little water in the radiator but no signs of external leakage is found. The oil level is found to be a little high and the oil appears to be thin.

A radiator tester is attached to the system and there is no sign of pressure or coolant leakage. The operation of the water pump is to be checked next. However, this test cannot be done because the engine will not start. The starter cannot turn the engine over. A quick check of the battery reveals that it is fully charged. Careful thought suggests that the problem is hydrostatic lockup. This is a condition in which a fluid fills the cylinder. Because a liquid cannot be compressed, the liquid prevents the piston from moving up.

To verify this, the spark plugs are removed. All plugs looked normal except cylinder #5.

It is wet with water. With the plugs out, the engine is cranked by the starter motor and water comes gushing out of the cylinder. The exact cause of the internal leak will be best identified by tearing down the engine. During disassembly, a crack in the engine block is found. This crack allowed the coolant to pass from a coolant passage in the block into the cylinder.

This leak is not detected by the radiator pressure test because when the engine is cold, little, if any, coolant leaks through the crack. The crack grows larger as the engine becomes hotter, allowing the cylinder to rapidly fill when it is hot. A new short block is put in the van and the problem is corrected.

KEY TERMS

Blowby	Flex-blades
Dry sump	Pressure relief valve
Electrochemical degradation (ECD)	Recovery tank
Electrolysis	Sludge
Expansion tank	Thermostat
Fan clutch	Wet sump

SUMMARY

- An engine's lubricating system must provide an adequate supply of oil to cool, clean, lubricate, and seal the engine. It also must remove contaminants from the oil and deliver oil to all necessary areas of the engine.
- Engine oil is stored in the oil pan or sump. The oil pump draws the oil from the sump and passes it through a filter where dirt is removed. The oil is then moved throughout the engine via oil passages or galleries. After circulating through the engine, the oil returns to the sump.
- The oil pump circulates oil through passages in the engine.
- An oil pump is a positive displacement pump and needs a pressure relief valve to prevent high pressures during high engine speeds.
- All of the oil that leaves the oil pump is directed to an oil filter.
- Excessive oil consumption can result from external and internal leaks or worn piston rings, valve seals, or valve guides. Internal leaks allow oil to enter the combustion chamber where it is burned.
- **Blowby** is a term used for the gases that escape the combustion chamber and enter the crankcase.
- When oil oxidizes, chemical compounds in the oil begin to chemically break down and solidify and form sludge.
- The fluid used as coolant today is a mixture of water and ethylene glycol-based antifreeze/coolant.
- Closed-cooling systems are cooling systems with an expansion or recovery tank.
- The purpose of the water pump is to move the coolant efficiently through the system.
- The radiator transfers heat from the engine to the air passing through it.
- The thermostat attempts to control the engine's operating temperature by routing the coolant either to the radiator or through the bypass or sometimes a combination of both.
- Radiator pressure caps keep the coolant from splashing out of the radiator and keep the coolant under pressure.
- For every pound of pressure put on the coolant, the boiling point is raised about 3°F (1.6°C).
- Coolant flows from the engine to the radiator and from the radiator to the engine through radiator hoses.
- A temperature indicator is mounted in the dashboard to alert the driver of an overheating condition.
- A hot liquid passenger heater is part of the engine's cooling system.
- Radiators for vehicles with automatic transmissions have a sealed oil cooler located in the coolant outlet tank.
- The cooling fan delivers additional air to the radiator to maintain proper cooling at low speeds and idle.
- To save power and reduce the noise levels, most late-model vehicles have an electrically driven cooling fan.
- The basic procedure for testing a vehicle's cooling system includes inspecting the radiator filler neck, inspecting the overflow tube for dents and other obstructions, testing for external leaks, and testing for internal leaks.
- Most radiator leak repairs require removing the radiator from the vehicle.
- The pressure cap should hold pressure in its range as indicated on the tester gauge dial for 1 minute.

- A thermostat can be tested in the engine or after it is removed.
 - Hoses should be checked for leakage, swelling, and chafing. Any hose that feels mushy or extremely brittle or shows signs of splitting when it is squeezed should be replaced.
 - The majority of water pump failures are attributed to leaks of some sort. Other failures can be attributed to bearing and shaft problems and an occasional cracked casting.
 - Electrolysis removes the protective layer on the inside of the radiator tubes, which can lead to serious engine failures. It occurs when there is improper grounding of electrical accessories and equipment.
 - Engine overheating can cause detonation, preignition, blown head gasket, OHC cam seizure and breakage, blown hoses, radiator leaks, cylinder damage due to swelling pistons, sticky exhaust valve stems, and engine bearing damage.
 - A radiator pressure can help identify the source of any leak in the cooling system as well as check the operation of a pressure cap.
 - Internal leaks can be verified with a combustion leak tester.
 - When replacing a thermostat, the replacement should always have the same temperature rating as the original.
 - The cooling system should be drained, flushed, and refilled with fresh coolant every 2 to 4 years.
 - Hybrid vehicles typically require a special coolant because the cooling system also cools the inverter assembly. Hybrids also require special service procedures.
5. What is ECD and what can result from it?
 6. *True or False?* To eliminate the drain of engine power during times when cooling fan operation is not needed, many of today's belt-driven fans have a fan clutch that prevents the operation of the fan when the engine and radiator are heated up.
 7. For every pound of pressure put on engine coolant, the boiling point of the coolant is raised about _____.
 - a. 2°F (1.1°C)
 - b. 3°F (1.6°C)
 - c. 4°F (2.2°C)
 - d. 5°F (2.7°C)
 8. In most automotive engines, the water pump is driven by the _____.
 - a. geartrain
 - b. oil pump
 - c. crankshaft
 - d. impeller
 9. When must a thermostat be fully opened?
 - a. at 3°F (1.6°C) above its temperature rating
 - b. at 3°F (–16°C) below its temperature rating
 - c. at 20°F (–6.6°C) above its opening temperature
 - d. at 20°F (–6.6°C) below its opening temperature
 10. Explain why a pressure relief valve is needed in an automotive oil pump.
 11. List five problems that can be caused by engine overheating.
 12. Cooling system hoses should be replaced when they are _____.
 - a. hard (brittle)
 - b. soft (spongy)
 - c. swollen
 - d. all of the above
 13. *True or False?* The presence of steam in the cooling system results from low coolant levels or air in the system.
 14. Which of the following is not a true statement about thermostats?
 - a. Faulty thermostats are often the cause of air pockets in the coolant passages.
 - b. They can also cause an increase in fuel consumption and poor engine performance.
 - c. If the thermostat is stuck open, the coolant may not reach the desired temperature because it is cooled before it gets hot.
 - d. If a thermostat is stuck closed, coolant will not flow between the engine and radiator and the engine will quickly overheat.
 15. Describe the procedure for using air bleed valves to purge air out of a cooling system.

REVIEW QUESTIONS

1. What is the most efficient way to increase a radiator's efficiency?
 2. What type of radiator pressure cap is found on today's vehicles?
 3. Describe the simple test used to determine whether the water pump is causing good circulation.
 4. Which of the following is a function of the engine's lubrication system?
 - a. hold an adequate supply of oil
 - b. remove contaminants from the oil
 - c. deliver oil to all necessary areas of the engine
 - d. all of the above
5. What is ECD and what can result from it?
 6. *True or False?* To eliminate the drain of engine power during times when cooling fan operation is not needed, many of today's belt-driven fans have a fan clutch that prevents the operation of the fan when the engine and radiator are heated up.
 7. For every pound of pressure put on engine coolant, the boiling point of the coolant is raised about _____.
 - a. 2°F (1.1°C)
 - b. 3°F (1.6°C)
 - c. 4°F (2.2°C)
 - d. 5°F (2.7°C)

ASE-STYLE REVIEW QUESTIONS

- While refilling an 8-quart (7.57 L) system with coolant: Technician A initially puts in 4 quarts (3.78 L) of straight coolant and tops it off with water. Technician B fills the system with the correct mixture, tightens the radiator cap, and then checks for leaks. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- Technician A says that excessive engine oil consumption can be caused by low oil levels. Technician B says that excessive oil consumption can be caused by worn valve guides. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- While checking for conditions that might cause coolant electrolysis: Technician A places the positive lead of a voltmeter into the coolant and connects the negative lead to a ground. Technician B checks for the presence of voltage in the coolant with the ignition off. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- While checking the operation of a water pump: Technician A uses a pressure tester to apply normal operating pressure to the system. If the pressure increases, the water pump is working. Technician B starts the engine and allows it to warm up. The upper radiator hose is squeezed and the engine accelerated. If a surge is felt in the hose, the pump is working. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- Technician A says that if the PCV valve or connecting hoses become clogged, excessive pressure will develop in the crankcase and can cause oil leaks. Technician B says that if the PCV valve or connecting hoses become clogged, oil may be pushed into the air cleaner or cause it to be drawn into the intake manifold. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- While bleeding air from a cooling system: Technician A loosens a heater hose at its highest point. Technician B uses air bleed valves. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- While diagnosing an engine that overheats after frequent hard accelerations: Technician A checks for a collapsed lower radiator hose. Technician B checks the cooling fan electrical circuit. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- While performing a cooling system service on a hybrid vehicle: Technician A disconnects the electric water pump. Technician B disables the high-voltage system before serving the engine. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- While discussing the causes of extreme engine bearing damage: Technician A says that contaminated and old engine oil could be the cause. Technician B says that a leaking radiator could be the cause. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- While diagnosing the cause of air bubbles in the coolant recovery tank: Technician A checks for a bad head gasket. Technician B checks the radiator cap. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B

BASICS OF ELECTRICAL SYSTEMS

CHAPTER

15

OBJECTIVES

- Explain the basic principles of electricity. ■ Define the terms normally used to describe electricity.
- Use Ohm's law to determine voltage, current, and resistance. ■ List the basic types of electrical circuits.
- Describe the differences between a series circuit and a parallel circuit. ■ Name the various electrical components and their uses in electrical circuits. ■ Describe the different kinds of automotive wiring.

There is often confusion concerning the terms *electrical* and *electronic*. In this book, electrical and electrical systems refer to wiring and electrical parts, such as generators, lights, and voltage regulators. **Electronics** means computers and other black box-type items used to control engine and vehicle systems.

A good understanding of electrical principles is important to proper diagnosis of any system that is monitored, controlled, or operated by electricity (**Figure 15-1**).

BASICS OF ELECTRICITY

Perhaps the one reason why some people find it difficult to understand electricity is that they cannot see it. By actually knowing what it is and what it is *not*, you can easily understand it. Electricity is not magic! It is something that takes place or can take place in everything you know. It not only provides power for lights, TVs, stereos, and refrigerators, it is also the basis for the communications between our brain and the rest of our bodies. Although electricity cannot be

Figure 15-1 Basic overview of an electrical system for a late-model car.

Figure 15-2 Electricity is the flow of electrons from one atom to another.

seen, the effects of it can be seen, felt, heard, and smelled. One of the most common displays of electricity is a lightning bolt. Lightning is electricity—a large amount of electricity. The power of lightning is incredible. Using the power from much smaller amounts of electricity to perform some work is the basis for an automobile's electrical system. Electricity cannot be seen because it is the movement of extremely small objects that move at the speed of light (186,282.397 miles [299,792,458 meters] per second).

Flow of Electricity

Electricity is the flow of electrons from one atom to another (**Figure 15-2**). The release of energy as one electron leaves the orbit of one atom and jumps into the orbit of another is electrical energy. The key to creating electricity is to provide a reason for the electrons to move to another atom.

There is a natural attraction of electrons to protons. Electrons have a negative charge and are attracted to something with a positive charge. When an electron leaves the orbit of an atom, the atom then has a positive charge. An electron moves from one atom to another because the atom next to it appears to be more positive than the one it is orbiting around.

An electrical power source provides for a more positive charge and, to allow for a continuous flow of electricity, it supplies free electrons. To have a continuous flow of electricity, three things must be present: an excess of electrons in one place, a lack of electrons in another place, and a path between the two places.

Two power or energy sources are used in an automobile's electrical system. These are based on a chemical reaction and **magnetism**. A car's battery is a source of chemical energy (**Figure 15-3**). A chemical reaction in the battery provides for an excess of electrons and a lack of electrons in another place. Batteries have two terminals, a positive and a negative. Basically, the negative terminal is the outlet for the electrons and the positive terminal is the inlet for the electrons to get to the protons. The chemical reaction in a battery causes a lack of electrons at the positive (+) terminal and an excess at the negative (−) terminal. This creates an electrical imbalance, causing

Figure 15-3 An automotive battery.

the electrons to flow through the path provided by a wire.

The chemical process in the battery continues to provide electrons until the chemicals become weak. At that time, either the battery has run out of electrons or all the protons are matched with an electron. When this happens, there is no longer a reason for the electrons to want to move to the positive side of the battery. To the electrons, it no longer looks more positive. Fortunately, the vehicle's charging system continuously restores the battery's supply of electrons. This allows the chemical reaction in the battery to continue indefinitely. In an electrical diagram, a battery is drawn as shown in **Figure 15-4**.

Electricity and magnetism are interrelated. One can be used to produce the other. Moving a wire (a conductor) through an already existing magnetic field (such as a permanent magnet) can produce electricity. This process of producing electricity

Figure 15-4 Symbol for a battery.

Figure 15-5 A late-model generator. Courtesy of Robert Bosch GmbH, www.bosch-presse.de

through magnetism is called **induction**. The heart of a vehicle's charging system is the AC generator (**Figure 15-5**). A magnetic field, driven by the crankshaft via a drive belt, rotates through a coil of wire, producing electricity. The amount of electricity produced depends on a number of things: the strength of the magnetic field, the number of wires that are passed by the magnetic field, and the speed at which the magnetic field moves past the wires.

Electricity is also produced by chemical, photo-electrical, thermoelectrical, and piezoelectrical reactions. These sources of electricity are used throughout a modern automobile. Most are the basis of operation for electronic sensors and are discussed as those sensors are introduced in this book. The two most common ways of producing electricity are through electromagnetic induction and chemical reaction. These are main topics of the chapters in this section of the book.

ELECTRICAL TERMS

Electrical **current** describes the movement or flow of electricity. The greater the number of electrons flowing past a given point in a given amount of time, the more current the circuit has. The unit for measuring electrical current is the **ampere**, usually called an amp. The term *ampere* was assigned to units of current in honor of André Ampère, who studied the relationship between electricity and magnetism. The instrument used to measure electrical current flow in a circuit is called an ammeter.

When electricity flows, millions of electrons are moving past any given point at the speed of light. The electrical charge of any one electron is extremely

small. It takes millions of electrons to make a charge that can be measured. In fact, 1 ampere of current means that 6.24 billion billion electrons are flowing past a given point in 1 second.

SHOP TALK

Engineers often express current flow in coulombs. One coulomb represents the amount of electric charge moved by a current of 1 ampere in 1 second. A coulomb represents $6.241\,509\,629\,152\,65 \times 10^{18}$ electrons.

There are two types of current: **direct current (DC)** and **alternating current (AC)**. In direct current, the electrons flow in one direction only. In AC, the electrons change direction at a fixed rate. Typically, an automobile uses DC, while the current in homes and buildings is AC. Some components of the automobile generate or use AC. These are discussed in later chapters.

There are many theories about the direction of current flow. The conventional theory states that current flows from positive to negative. The electron theory says current moves from negative to positive. And the hole-flow theory basically says something is moving in both directions. Remember that a *theory* is *not* a *fact*. It is a concept that is yet to be proved wrong or right. Therefore, only one theory about current flow is correct and the rest are wrong. For the purposes of this book and for your own understanding of electricity, current flow (**Figure 15-6**) is described as moving from a point of higher potential (voltage) to a point of lower potential (voltage). This statement may not be absolutely correct, but it is sound and is based on what can be observed.

Voltage is electrical pressure (**Figure 15-7**). It is the force developed by the attraction of the electrons to protons. The more positive one side of the circuit is, the more voltage is present in the circuit. Voltage does not flow; it is the pressure that causes current flow. To have current flow, some force is needed to move the electrons between atoms. This force is the

Figure 15-6 Current moves from a point of higher potential to a point of lower potential.

Figure 15-7 Voltage is electrical pressure.

Figure 15-8 Common symbol for an ohm.

pressure that exists between a positive and negative point within an electrical circuit. This force, also called **electromotive force (EMF)**, is measured in units called volts. One volt is the amount of pressure required to move 1 ampere of current through a resistance of 1 ohm. Voltage is measured by an instrument called a voltmeter. The unit of measurement for electrical pressure was so named to honor Alessandro Volta, who, in 1800, made the first electrical battery.

When any substance flows, it meets **resistance**. The resistance to electrical flow can be measured. The resistance to current flow produces heat. This heat can be measured to determine the amount of resistance. A unit of measured resistance is called an **ohm**. The common symbol for an ohm is shown in **Figure 15-8**. Resistance can be measured by an instrument called an ohmmeter.

Alternating Current

AC constantly changes in voltage and direction. If a graph is used to represent the amount of DC voltage

Figure 15-9 The difference between DC and AC.

available from a battery during a fixed period, the line on the graph will be flat, which represents a constant voltage. If AC voltage is shown on a graph, it will appear as a **sine wave** (**Figure 15-9**). The sine wave shows AC changing in amplitude (strength) and direction. The highest positive voltage equals the highest negative voltage. The movement of the AC from its peak at the positive side of the graph to the negative side and then back to the positive peak is commonly referred to as “peak-to-peak” value. This value represents the amount of voltage available at a point. During each complete cycle of AC, there are always two maximum or peak values, one for the positive half-cycle and the other for the negative half-cycle. The difference between the peak positive value and the peak negative value is used to measure AC voltages (**Figure 15-10**).

Figure 15-10 The action and measurement of alternating current.

AC does not have a constant value; therefore, as it passes through a resistance, nearly 29% less heat is produced when compared to DC. This is one reason that AC is preferred over DC when powering motors and other electrical devices.

The lack of heat also causes us to look at AC values differently than the same values in a DC circuit. AC has an effective value of 1 ampere when it produces heat in a given resistance at the same rate as does 1 ampere of DC. The effective value of an AC is equal to 0.707 times its maximum or peak current value. Because AC is caused by an alternating voltage, the ratio of the effective voltage value to the maximum voltage value is the same as the ratio of the effective current to the maximum current, or 0.707 times the maximum value. AC voltage measurements are often expressed in terms of root mean square (RMS) values.

AC voltage and current change constantly and their values must be viewed as average or effective. When AC is applied to a resistance, as the actual voltage changes in value and direction, so does the current. In fact, the change of current is in phase with the change in voltage. An “in-phase” condition exists when the sine waves of voltage and current are precisely in step with one another. The two sine waves go through their maximum and minimum points at the same time and in the same direction. In some circuits, several sine waves can be in phase with each other.

If a circuit has two or more voltage pulses but each has its own sine wave that begins and ends its cycle at a different time, the waves are “out of phase.” If two sine waves are 180 degrees out of phase, they will cancel each other out if they have the same voltage and current. If two or more sine waves are out of phase but do not cancel each other, the effective voltage and current are determined by the position and direction of the sine wave at a given point within the circuit (Figure 15-11).

Figure 15-11 The sine waves of three-phase AC.

Circuit Terminology

An electrical circuit is considered complete when there is a path that connects the positive and negative terminals of the electrical power source. A completed circuit is called a **closed circuit**, whereas an incomplete circuit is called an **open circuit**. When a circuit is complete, there is **continuity**. Conductors are drawn in electrical diagrams as a line connecting two points, as shown in Figure 15-12.

In a complete circuit, the flow of electricity can be controlled and applied to do useful work, such as light a headlamp or turn over a starter motor. Components that use electrical power put a load on the circuit and consume electrical energy. These components are often referred to as electrical loads. Loads are drawn in electrical diagrams as a symbol representing the part or as a resistor. The typical drawing of a resistor is shown in Figure 15-13.

The amount of current that flows in a circuit is determined by the resistance in that circuit. As resistance goes up, the current goes down. The total resistance in a circuit determines how much current will flow through the circuit. The energy used by a load is measured in volts. Amperage stays constant in a circuit but the voltage drops as it powers a load. Measuring voltage drop tells how much energy is being consumed by the load.

The amount of electricity consumed by a load is normally called electrical power usage or watts. One watt is equal to 1 volt multiplied by 1 ampere. The formula for determining the amount of power consumed by a load is the amount of current through the load multiplied by the voltage drop across the load.

Grounding the Load Most automotive electrical circuits use the chassis as a conductor for the negative side of the battery through the battery’s ground wire, as shown in Figure 15-14. Current passes from the battery, through the load, through the metal frame, and back to the battery. Using the frame as a return path or ground eliminates the need for a separate ground wire at each component. Without **grounding**

Figure 15-12 Conductors are drawn as lines from one point to another.

Figure 15-13 Symbol for a resistor.

Figure 15-14 Most automotive electrical circuits use the chassis as the conductor for the negative side of the battery.

parts to the frame, hundreds of additional wires would be needed to complete the individual circuits.

Major components, such as the engine block and transmission case, also have a grounding wire connected to the frame. This provides a ground circuit for parts that are mounted directly to the block (**Figure 15-15**) or transmission. Other parts have a separate ground wire that connects the body of the part to the frame, engine, or transmission. These connections are called **chassis ground** connections. The wire that serves as the contact to the chassis is commonly called the **ground wire** or lead.

In wiring diagrams, chassis ground connections are drawn to show the normal type of ground connection for that part (**Figure 15-16**). When the ground is made through the mounting of the component, the connection is represented in the drawing A. When

Figure 15-15 Many electrical parts are grounded through their mounting to the engine, transmission, or frame.

Figure 15-16 Symbols for grounds: (A) made through the component's mounting (B) made by a remote wire.

Figure 15-17 To ensure good grounding, manufacturers use a network of common grounding terminals and wires.

the ground is made by a wire that connects to the chassis, the connection is shown as B.

The increased use of plastics and other nonmetallic materials in body panels and engine parts has made electrical grounding more difficult. To ensure good grounding, some manufacturers use a network of common grounding terminals and wires (**Figure 15-17**).

OHM'S LAW

In 1827, a German mathematics professor, Georg Ohm, published a book that included his explanation of the behavior of electricity. His thoughts have become the basis for a true understanding of electricity. He found it takes 1 volt of electrical pressure to push 1 ampere of electrical current through 1 ohm of resistance. This statement is the basic law of electricity. It is known as **Ohm's law**.

A simple electrical circuit is a load connected to a voltage source by conductors. The resistor could be a fog light, the voltage source could be a battery, and the conductor could be a copper wire (**Figure 15-18**).

In any electrical circuit, current (I), resistance (R), and voltage (E) are mathematically related. This relationship is expressed in a mathematical statement of Ohm's law. Ohm's law can be applied to the entire circuit or to any part of a circuit. When any two factors are known, the third factor can be found by using Ohm's law. Using the circle shown in **Figure 15-19**, you can easily find the formula for calculating the unknown element. By covering the element you need to find, the necessary formula is shown in the circle.

To find voltage, cover the E (**Figure 15-20**). The voltage (E) in a circuit is equal to the current (I) in amperes multiplied by the resistance (R) in ohms.

Figure 15-18 A simple circuit consists of a voltage source, conductors, and a resistance or load.

Figure 15-19 Ohm's law.

Figure 15-20 To find voltage, cover the *E* and use the exposed formula.

Figure 15-21 To find current, cover the *I* and use the exposed formula.

Figure 15-22 To find resistance, cover the *R* and use the exposed formula.

To find current, cover the *I* (**Figure 15-21**). The current (amperage) in a circuit equals the voltage divided by the resistance (in ohms).

To find resistance, cover the *R* (**Figure 15-22**). The resistance of a circuit (in ohms) equals the voltage divided by the current (in amperes).

Figure 15-23 Same circuit as shown in Figure 15-18 but this one has a corroded wire, represented by the additional resistor.

It is very important for technicians to understand Ohm's law. It explains how an increase or decrease in voltage, resistance, or current affects a circuit.

For example, if the fog light in Figure 15-18 has a 6-ohm resistance, how many amperes does it use to operate? Since cars and light trucks have a 12-volt battery and you know two of the factors in the fog light circuit, it is simple to solve for the third.

$$\begin{aligned} I(\text{unknown}) &= \frac{E(12 \text{ volts})}{R(6 \text{ ohms})} \\ I &= \frac{12}{6} \\ I &= 2 \text{ amperes} \end{aligned}$$

In a clean, well-wired circuit, the fog lights will draw 2 amperes of current. What would happen if resistance in the circuit increases due to corroded or damaged wire or connections? If the corroded connections add 2 ohms of resistance to the fog light circuit, the total resistance is 8 ohms (**Figure 15-23**). The amount of current flowing through the circuit for the lights decreases.

$$\begin{aligned} I &= \frac{12}{6 + 2} = \frac{12}{8} \\ I &= 1.5 \text{ amperes} \end{aligned}$$

If the lights are designed to operate at 2 amperes, this decrease to 1.5 amperes causes them to burn dimly. Cleaning the corrosion away or installing new wires and connectors eliminates the unwanted resistance; the correct amount of current will flow through the circuit, allowing the lamp to burn as brightly as it should.

Voltage Drops

Voltage drop is the amount of voltage required to cause current flow through a load. Electrical energy is changed to another form of energy as it flows through a load and the voltage leaving the load is lower than it was when it entered. The amount of voltage dropped by a load depends on the circuit's current and the resistance of the load. Voltage drop can be calculated by using Ohm's law. If the resistance of the load and the circuit's current are known, the voltage drop is the product of the two. If there is only one load in the circuit, the voltage drop will equal the source voltage.

Figure 15-24 All of the available voltage is dropped by the loads in the circuit. The amount of drop depends on the resistance of the load.

When there is more than one load, the voltage drop will vary with the values of the loads. For example, if a 12-volt circuit has a 3-ohm load and a 9-ohm load, the total current will be 1 ampere and the total resistance will be 12 ohms. The voltage drop across the 3-ohm load will be 1×3 , which equals 3 volts. The drop across the other load will be 1×9 , or 9 volts (**Figure 15-24**).

All of the available voltage in a circuit is dropped by the loads; therefore, 0 volts is present at the negative connection of the power source.

AC Circuits In AC circuits, the actual resistance of a load is called its **impedance**. Electrical impedance, like resistance, is measured in ohms and is simply defined as the operating resistance of a load. In addition to the static resistance of a load, additional opposition to AC current flow results from its interaction with magnetic fields within the conductor. Voltage drop in an AC circuit is the product of the current and the impedance (Z) of the circuit or load. It is expressed by the formula $E = I \times Z$ (**Figure 15-25**).

Power and Watt's Law

Watt's law is the name given to the formula that calculates the electrical power (P) used by a load. The

Figure 15-25 In alternating current circuits, the actual resistance of a load is called its impedance (Z).

Figure 15-26 Electrical power is calculated by multiplying voltage by current.

law is expressed by the mathematical formula of $P = I \times E$. In other words, power equals current multiplied by voltage. Electric power is expressed in **watts** and represents the rate at which electrical energy is converted to another form of energy. Electrical energy can be converted into sound, heat, light, or motion.

If two loads have the same available voltage, the load with the lowest resistance will use the most power. For example, a 40-W household light bulb has a higher resistance than a 100-W bulb.

Although power measurements are rarely needed in automotive service, knowing the power requirements of light bulbs, electric motors, and other components is sometimes useful when troubleshooting electrical systems. Looking back at the example of the fog light circuit, the amount of power used by the fog light can be calculated (**Figure 15-26**).

$$P = 12 \text{ volts} \times 2 \text{ amperes}$$

$$P = 24 \text{ watts}$$

The normal fog light uses 24 watts of power, whereas the corroded fog light circuit results in the following:

$$P = 12 \text{ volts} \times 1.5 \text{ amperes}$$

$$P = 18 \text{ watts}$$

This reduction in power explains the decrease in bulb brightness.

CIRCUITS

A complete electrical circuit exists when electrons flow along a path between two points. In a complete circuit, resistance must be low enough to allow the available voltage to push electrons between the two points. Most automotive circuits contain five basic parts.

1. Power sources, such as a battery or alternator, that provide the energy needed to cause electron flow
2. Conductors, such as copper wires, that provide a path for current flow
3. Loads, which are devices that use electricity to perform work, such as light bulbs, electric motors, or resistors

4. Controllers, such as switches or relays, that control or direct the flow of electrons
5. Circuit protection devices, such as fuses, circuit breakers, and fusible links

There are also three basic types of circuits used in automotive electrical systems: series circuits, parallel circuits, and series-parallel circuits. Each circuit type has its own characteristics regarding amperage, voltage, and resistance.

Series Circuits

A **series circuit** consists of one or more resistors connected to a voltage source with only one path for electron flow. For example, a simple series circuit consists of a resistor (2 ohms in this example) connected to a 12-volt battery (**Figure 15-27A**). The current can be determined by applying Ohm's law.

$$I = \frac{E}{R} = \frac{12}{2} = 6 \text{ amperes}$$

Another series circuit may contain a 2-ohm resistor and a 4-ohm resistor connected to a 12-volt battery (**Figure 15-27B**). The word *series* is given to a circuit in which the same amount of current is present throughout the circuit. The current that flows through one resistor also flows through other resistors in the circuit. As that amount of current leaves the battery, it flows through the conductor to the first resistor. At the resistor, some electrical energy or voltage is consumed as the current flows through it. The decreased amount of voltage is then applied to the next resistor as current flows to it. By the time the current is flowing in the conductor leading back to the battery, all voltage has been dropped. All of the source voltage available to the circuit is dropped by the resistors in the circuit.

In a series circuit, the total amount of resistance in the circuit is equal to the sum of all the individual resistors. In the circuit in **Figure 15-27B**, the total

Figure 15-27 In a series circuit, the same amount of current flows through the entire circuit.

circuit resistance is $4 + 2 = 6$ ohms. Based on Ohm's law, current is $I = E/R = 12/6 = 2$ amperes. In a series circuit, current is constant throughout the circuit. Therefore, 2 amps of current flows through the conductors and both resistors.

Ohm's law can be used to determine the voltage drop across parts of the circuit. For the 2-ohm resistor, $E = IR = 2 \times 2 = 4$ volts. For the 4-ohm resistor, $E = 2 \times 4 = 8$ volts. The sum of all voltage drops in a series circuit must equal the source voltage, or $4 + 8 = 12$ volts.

An ammeter connected anywhere in this circuit will read 2 amperes, and a voltmeter connected across each of the resistors will read 4 volts and 8 volts, as shown in **Figure 15-28**.

All calculations for a series circuit work in the same way no matter how many resistors there are in series. Consider the circuit in **Figure 15-29**. This circuit has four resistors in series with each other. The total resistance is 12 ohms (5 ohms + 2 ohms + 4 ohms + 1 ohm). Using Ohm's law, we can see that the circuit current is 1 amp ($I = E/R = 12/12 = 1$ amp). We can also use Ohm's law to determine the voltage drop across each resistor in the circuit. For example, since the circuit current is 1 amp, 4 volts are dropped by the 4-ohm resistor ($E = I \times R = 1 \text{ amp} \times 4 \text{ ohms} = 4 \text{ volts}$).

Figure 15-28 Measuring the current and voltage drops in the circuit.

Figure 15-29 Values in the series circuit.

A series circuit is characterized by the following four facts:

1. The circuit's current is determined by the total amount of resistance in the circuit; it is constant throughout the circuit.
2. The voltage drops across each resistor are different if the resistance values are different.
3. The sum of the voltage drops equals the source voltage.
4. The total resistance is equal to the sum of all resistances in the circuit.

Parallel Circuits

A **parallel circuit** provides two or more different paths for the current to flow through. Each path has separate resistors (loads) and can operate independently of the other paths. The different paths for current flow are commonly called the legs of a parallel circuit.

A parallel circuit is characterized by the following facts:

1. Total circuit resistance is always lower than the resistance of the leg with the lowest total resistance.
2. The current through each leg will be different if the resistance values are different.
3. The sum of the current on each leg equals the total circuit current.
4. The voltage applied to each leg of the circuit will be dropped across the legs if there are no loads in series with the parallel circuit.

Consider the circuit shown in **Figure 15-30**. Two 3-ohm resistors are connected to a 12-volt battery. The resistors are in parallel with each other, since the battery voltage (12 volts) is applied to each resistor and they have a common negative lead. The current through each resistor or leg can be determined by applying Ohm's law. For the 3-ohm resistors, $I = E/R = 12/3 = 4$ amperes. Therefore, the total circuit current supplied by the battery is $4 + 4 = 8$ amperes. Using

Figure 15-30 A simple parallel circuit.

Figure 15-31 A parallel circuit with voltage drops shown.

Ohm's law, we find that 12 volts are dropped by both resistors (**Figure 15-31**).

Resistances are not added up to calculate the total resistance in a parallel circuit. Rather, they can be determined by dividing the product of their ohm values by the sum of their ohm values. This formula works when the circuit has two parallel legs.

$$\frac{3 \text{ ohms} \times 3 \text{ ohms}}{3 \text{ ohms} + 3 \text{ ohms}} = \frac{9}{6} = 1.5 \text{ ohms}$$

Total resistance can also be calculated by using Ohm's law if you know the total circuit current and the voltage ($R = E/I = 12/8 = 1.5$ ohms).

Consider another parallel circuit, **Figure 15-32**. In this circuit there are two legs and four resistors. Each leg has two resistors in series. One leg has a 4-ohm and a 2-ohm resistor. The total resistance on that leg is 6 ohms. The other leg has a 1-ohm and a 2-ohm resistor. The total resistance of that leg is 3 ohms. Therefore, we have 6 ohms in parallel with 3 ohms.

Current flow through the circuit can be calculated by different methods. Using Ohm's law, we know that $I = E/R$. If we take the total resistance of each leg and divide it into the voltage, we then know the current through that leg. Since total circuit current is equal to the sum of the current flows through each leg, we simply add the current across each leg together. This will give us total circuit current.

$$\text{Leg 1: } I = E/R = 12/6 = 2 \text{ amps}$$

$$\text{Leg 2: } I = E/R = 12/3 = 4 \text{ amps}$$

$$2 \text{ amps} + 4 \text{ amps} = 6 \text{ amps} = \text{total circuit current}$$

Circuit current can also be determined by finding the total resistance of the circuit. To do this, the

Figure 15-32 Series circuits within a parallel circuit.

Figure 15-33 A parallel circuit with four legs.

product-over-sum formula is used. By dividing this total into the voltage, total circuit current is known.

$$\frac{\text{Leg 1} \times \text{Leg 2}}{\text{Leg 1} + \text{Leg 2}} = \frac{6 \times 3}{6 + 3} = \frac{18}{9} = 2 \text{ ohms}$$

since $I = E/R$, $I = 12/2$, $I = 6$ amps (total circuit current)

When a circuit has more than two legs, the reciprocal formula should be used to determine total circuit resistance. The formula follows:

$$\frac{1}{\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \dots + \frac{1}{R_n}}$$

To demonstrate how to use this formula, consider the circuit in **Figure 15-33**. Here is a parallel circuit with four legs. The resistances across each leg are 4 ohms, 3 ohms, 6 ohms, and 4 ohms. Using the reciprocal formula, we will find that the total resistance of the circuit is 1 ohm. (Note that the total resistance is lower than the leg with the lowest resistance.)

$$\frac{1}{\frac{1}{4} + \frac{1}{3} + \frac{1}{6} + \frac{1}{4}} = \frac{1}{\frac{3}{12} + \frac{4}{12} + \frac{2}{12} + \frac{3}{12}} = \frac{1}{\frac{12}{12}} = \frac{1}{1} = 1$$

The total of this circuit could also have been found by calculating the current across each leg then adding them together to get the total circuit current. Using Ohm's law, if you divide the voltage by the total circuit current, you will get total resistance.

$$\text{Leg 1: } I = E/R = 12/4 = 3 \text{ amps}$$

$$\text{Leg 2: } I = E/R = 12/3 = 4 \text{ amps}$$

$$\text{Leg 3: } I = E/R = 12/6 = 2 \text{ amps}$$

$$\text{Leg 4: } I = E/R = 12/4 = 3 \text{ amps}$$

Total circuit current = $3 + 4 + 2 + 3 = 12$ amps;
then,

$$R = E/I = 12/12 = 1 \text{ ohm}$$

Series-Parallel Circuits

In a **series-parallel circuit**, both series and parallel combinations exist in the same circuit. If you are faced with the task of calculating the values in a series-parallel circuit, determine all values of the parallel

Figure 15-34 In a series-parallel circuit, the sum of the currents through the legs must equal the current through the series part of the circuit.

circuit(s) first. By looking carefully at a series-parallel circuit, you will find that it is nothing more than one or more parallel circuits in series with each other or in series with some other resistance.

A series-parallel circuit is illustrated in **Figure 15-34**. The 6- and 3-ohm resistors are in parallel with each other and together are in series with the 2-ohm resistor.

The total current in this circuit is equal to the voltage divided by the total resistance. The total resistance can be determined as follows. The 6- and 3-ohm parallel resistors in **Figure 15-35** are equivalent to a 2-ohm resistor, since $(6 \times 3)/(6 + 3) = 2$. This equivalent 2-ohm resistor is in series with the other 2-ohm resistor. To find the total resistance, add the two resistance values together. This gives a total circuit resistance of 4 ohms ($2 + 2 = 4$ ohms). The total current, therefore, is $I = 12/4 = 3$ amperes. This means that 3 amps of current is flowing through the 2-ohm resistor in series and 3 amps are divided between the resistors in parallel. In series-parallel circuits, the sum of the currents, flowing in the parallel legs, must equal that of the series resistors' current.

To find the current through each of the resistors in parallel, find the voltage drop across those resistors first. With 3 amperes flowing through the 2-ohm resistor, the voltage drop across this resistor is $E = IR = 3 \times 2 = 6$ volts, leaving 6 volts across the 6- and 3-ohm resistors. The current through the 6-ohm resistor is $I = E/R = 6/6 = 1$ ampere, and through the 3-ohm resistor is $I = 6/3 = 2$ amperes. The sum of these two current values must equal the total circuit current, and it does,

Figure 15-35 The circuit in Figure 15-34 with voltage drops shown.

$1 + 2 = 3$ amperes (Figure 15–35). The sum of the voltage drops across the parallel part of the circuit and the series part must also equal source voltage.

Kirchhoff's Law

In the 1840s, German physicist Gustav Kirchhoff described two laws on the behavior of electricity. Both of these laws relate to Ohm's law and help define the characteristics of series and parallel circuits.

Kirchhoff's "voltage law" basically states that the sum of the voltage drops in a closed circuit equals the voltage applied to that circuit. This directly describes the behavior of a series circuit. This law also describes the characteristics of more complex circuits in which there are positive and negative voltages. These are not discussed here.

Kirchhoff's "current law" explains the behavior of current in a parallel circuit. This law can be safely stated as: "At any junction point in a circuit, the current arriving to that point is equal to the current leaving." If 10 amperes of current arrives at the point in a circuit where a parallel leg is added to the circuit, the 10 amps will be divided according to the resistance of each leg, but a total of 10 amps will be present at the junction that ties the legs together again. In other words, the sum of the branch currents is equal to the total current entering the branches as well as the total current leaving the branches.

CIRCUIT COMPONENTS

Automotive electrical circuits contain a number of different electrical devices. The more common components are outlined in the following sections.

Power Sources

Most of today's vehicles operate with basically 12-volt electrical systems. The word *basically* is used because the battery is rated at 12 volts but stores 12.6 volts, and the charging system puts out about 14 volts while the engine is running. Because the charging system is the primary source of electrical power, it is fair to say that an automobile's electrical system is a 14-volt system.

In 1954, General Motors equipped its Cadillac with a 12-volt system. Prior to 1954, vehicles had 6-volt systems. The electrical demands of accessories, such as power windows and seats, put a severe strain on the 6-volt battery and charging system. With a 12-volt system, the charging system had to work less hard and there was plenty of electrical power for the electric accessories.

The increase in voltage also allowed wire sizes to decrease because the amperage required to power things was reduced. To explain this, consider an

accessory that required 20 amps to operate in a 6-volt system (120 watts). When the voltage was increased to 12 volts, the system only drew 10 amperes.

Today we are faced with the same situation. The use of computers and the need to keep their memories fresh has put a drain on the battery even when the engine is not running. The number of electrical accessories also has and will continue to grow.

Today's vehicles are very sensitive to voltage change. In fact, their overall efficiency depends on a constant voltage. The demands of new technology make it difficult to maintain a constant voltage, and engineers have determined that system voltage must be increased to meet those demands. As vehicles evolve, emissions, fuel economy, comfort, convenience, and safety features will put more of a drain on the electrical system. This increased demand results from converting purely mechanical systems into electromechanical systems, such as steering, suspension, and braking systems, as well as new safety and communication systems. It has been estimated that in a few years the demand for continuous electrical power will be 3,000 to 7,000 W. Current 14-volt systems are rated at 800 to 1,500 W.

To meet these demands there are two possible solutions: increase the amperage capacity of the battery and charging system or increase system voltage.

Higher-amperage batteries and generators are only a Band-Aid solution. Because the generator is driven by engine power, more power from the engine will be required to keep the higher-capacity battery charged. Therefore, overall efficiency will decrease.

By moving to a higher system voltage, the battery will need to be larger and heavier. However, because system amperage will be lower, wire size will be smaller and perhaps the weight gain at the battery will be offset by the decreased weight of the wiring.

All of the advantages of moving from 6- to 12-volt systems apply to the move from 12 volts to 42 volts. But why 42 volts? Forty-two volts represent three 12-volt batteries. Engineers decided to take advantage of the fact that a 12-volt battery receives a 14-volt charge ($3 \times 14 \text{ volts} = 42 \text{ volts}$). Forty-two-volt systems are also desirable for safety reasons. Sixty volts can stop a person's heart; therefore, 42-volt systems allow for a margin of safety.

Forty-two-volt systems are based on a single 36-volt battery but have dual voltage systems (**Figure 15–36**). Part of the vehicle is powered by 12 to 14 volts and the rest by 36 to 42 volts. The battery has two positive connectors, one for each voltage, or the voltage is divided by a converter. The split voltage system provides 42 volts for high-voltage applications such as the starter/generator, power steering,

Figure 15-36 A split voltage arrangement providing 14 and 42 volts from a 36-volt battery.

air conditioning, traction control, brake, and engine cooling systems. The 14-volt system powers low-load systems, such as lights, power door locks, radios, and navigation systems.

High-Voltage Systems The battery in a hybrid or fuel cell vehicle serves a different purpose than a battery in a conventional vehicle. In a conventional vehicle, the battery's primary purpose is to provide a short powerful burst of power to start the engine. This type of battery is typically called a **starting battery**. In hybrid vehicles, the batteries provide continuous current to power electric motors and must be able to accept quick and frequent recharges.

A starting battery is also found in some hybrids in addition to a **high-voltage (HV) battery** (Figure 15-37). The starting battery is used to start the engine, whereas the HV battery is used to power the electric motors. The HV system may also be used to power some accessories. In these vehicles, the starting battery is also used as the power source for normal accessories, such as lights.

Figure 15-38 A high-voltage battery pack is made up of many individual battery cells.

Because there is no engine in a fuel cell electric vehicle (FCEV), there is no need for a starting battery. These vehicles are typically equipped with HV batteries.

Hybrid vehicles typically run on 42 to 600 volts. Hundreds of individual battery cells, each about the size of a flashlight battery, are connected together to store and provide the needed power (Figure 15-38). The HV batteries used in hybrids are called battery packs. Many different types of batteries are available and under development to exceed the needs of these vehicles. In addition to batteries, some hybrid vehicles are equipped with ultracapacitors, which store and provide electrical energy.

HV is needed in hybrids to eliminate the need for extremely large cables and wiring. Also, keeping the required amperage low is easier on the batteries. A vehicle equipped with a starter/generator can be considered a mild hybrid and it relies on a 42-volt system. Functions such as stop-start, regenerative braking, and electrical assist are common to full and mild hybrid vehicles.

Only full hybrids have the ability to move in an electric-only mode. A full hybrid vehicle has a much

Figure 15-37 A hybrid vehicle with two battery packs.

higher voltage system than a mild hybrid; therefore, the battery is capable of providing much more power, more frequently, and for longer periods.

Resistors

As shown in the explanation of simple circuit design, resistors are used to limit current flow (and thereby voltage) in circuits where full current flow and voltage are not needed or desired. Resistors are devices specially constructed to put a specific amount of resistance into a circuit. In addition, some other components use resistance to produce heat and even light. An electric window defroster is a specialized type of resistor that produces heat. Electric lights are resistors that get so hot they produce light.

Automotive circuits typically contain these types of resistors: fixed value, stepped or tapped, and variable.

Fixed value resistors are designed to have only one rating, which should not change. These resistors are used to decrease the amount of voltage applied to a component, such as an ignition coil. Often manufacturers use a special wire, called **resistor wire**, to limit current flow and voltage in a circuit. This wire looks much like normal wire but is not a good conductor and is marked as a resistor.

Tapped or stepped resistors are designed to have two or more fixed values available by connecting wires to the several taps of the resistor. Heater motor resistor packs, which provide for different fan speeds, are an example of this type of resistor (Figure 15-39).

Variable resistors are designed to have a range of resistances available through two or more taps and a control. Two examples of this type of resistor are **rheostats** and **potentiometers**. Rheostats (Figure 15-40) have two connections, one to the fixed end of a resistor and one to a sliding contact with the resistor. Moving the control moves the sliding contact away from or toward the fixed end tap,

Figure 15-39 A stepped resistor.

Figure 15-40 A rheostat.

Figure 15-41 A potentiometer.

Figure 15-42 Voltage across a potentiometer.

increasing or decreasing the resistance. Potentiometers (Figure 15-41) have three connections, one at each end of the resistance and one connected to a sliding contact with the resistor. Moving the control moves the sliding contact away from one end of the resistance but toward the other end. These are called potentiometers because different amounts of potential or voltage can be sent to another circuit. As the sliding contact moves, it picks up a voltage equal to the source voltage minus the amount dropped by the resistor, so far (Figure 15-42).

Another type of variable resistor is the **thermistor**. This type of resistor is designed to change its resistance value as its temperature changes. Although most resistors are carefully constructed to maintain their rating within a few ohms through a range of temperatures, the thermistor is designed to change its rating. Thermistors are used to provide compensating voltage in components or to determine temperature. As a temperature sensor, the thermistor is connected to a voltmeter calibrated in degrees. As the temperature rises or falls, the resistance also changes, and so does the voltage in the circuit. These changes are read on the temperature gauge. Thermistors are also commonly used to sense temperature and send a signal back to a control unit. The control unit interprets the signal as a temperature value (Figure 15-43).

SHOP TALK

There are two basic types of thermistors: negative temperature coefficient (NTC) and positive temperature coefficient (PTC). An NTC thermistor is one in which the resistance decreases with an increase in temperature. A PTC thermistor is one in which the resistance increases with an increase in temperature. To understand how a circuit works, begin by identifying the type used in the circuit.

Figure 15-43 A thermistor is used to measure temperature. The sensing unit measures the change in resistance and translates this into a temperature value.

Figure 15-44 Electrical symbols for common circuit protection devices.

Circuit Protective Devices

When overloads or shorts in a circuit cause too much current to flow, the wiring in the circuit heats up, the insulation melts, and a fire can result, unless the circuit has some kind of protective device. Fuses, fuse links, maxi-fuses, and circuit breakers are designed to provide protection from high current. They may be used singly or in combination. Typical symbols for protection devices are shown in **Figure 15-44**.

WARNING!

Fuses and other protection devices normally do not wear out. They go bad because something went wrong. Never replace a fuse or fusible link, or reset a circuit breaker, without finding out why it went bad.

Fuses There are three basic types of fuses in automotive use: cartridge, blade, and ceramic (**Figure 15-45**). The **cartridge fuse** is found on most older domestic cars and a few imports. It is composed of a strip of low temperature melting metal enclosed in a transparent glass or plastic tube. Late-model domestic vehicles and many imports use **blade** or **spade fuses**. The **ceramic fuse** was used on many European imports. The core is a ceramic insulator with a conductive metal strip along one side.

Fuses are rated by the current at which they are designed to blow. A three-letter code is used to

Figure 15-45 (A) Blade fuse, (B) ceramic fuse, and (C) cartridge fuse.

indicate the types and sizes of fuses. Blade fuses have codes ATC or ATO. All glass SFE fuses have the same diameter, but the length varies with the current rating. Ceramic fuses are available in two sizes, code GBF (small) and the more common code GBC (large). The amperage rating is also embossed on the insulator. Codes, such as AGA, AGW, and AGC, indicate the length and diameter of the fuse. Fuse lengths in each of these series are the same, but the current rating can vary. The code and the current rating are usually stamped on the end cap.

The current rating for blade fuses is indicated by the color of the plastic case (**Table 15-1**). In addition, it is usually marked on the top. The insulator on ceramic fuses is color coded to indicate different current ratings.

Three basic types of blade fuses are found on today's vehicles: the standard blade, the minifuse, and the maxi-fuse. The minifuse is the commonly used circuit protection device. Minifuses are available in ratings from 5 to 30 amps. The maxi-fuse is a serviceable replacement for a fusible link cable. It is used in circuits that have high operating current. Maxi-fuses are available in 2–100 amp ratings; the most common is the 30 amp.

40	amber
50	red
60	blue

Fuses are located in a box or panel (Figure 15-46), usually under the dashboard, behind a panel in the foot well, or in the engine compartment. Fuses are generally numbered, and the main components abbreviated. On late-model cars, there may be icons or symbols indicating which circuits they serve. This identification system is covered in more detail in the owner's and service manuals.

Fuse Links Fuse or fusible links are used in circuits when limiting the maximum current is not extremely critical. They are often installed in the positive battery lead to the ignition switch and other circuits that have power with the key off. Fusible links are normally

Figure 15-46 Typical fuse box or panel.

found in the engine compartment near the battery. Fusible links are also used when it would be awkward to run wiring from the battery to the fuse panel and back to the load.

A fuse link (Figure 15-47) is a short length of small-gauge wire installed in a conductor. Because the fuse link is a lighter gauge of wire than the main conductor, it melts and opens the circuit before damage can occur in the rest of the circuit. Fuse link wire is covered with a special insulation that bubbles when it overheats, indicating that the link has melted.

CAUTION!

Always disconnect the battery ground cable prior to servicing any fuse link.

Maxi-Fuses Many late-model vehicles use maxi-fuses instead of fusible links. Maxi-fuses look and operate like two-prong, blade, or spade fuses, except that they are much larger (Figure 15-48) and can handle more current. Maxi-fuses are usually located in their own underhood fuse block.

Figure 15-47 A typical fuse link.

Maxi-fuses allow the vehicle's electrical system to be broken down into smaller circuits that are easy to diagnose and repair. For example, in some vehicles a single fusible link controls one-half or more of all circuitry. If it burns out, many electrical systems are lost. By replacing this single fusible link with several maxi-fuses, the number of systems lost due to a problem in one circuit is drastically reduced. This makes it easy to pinpoint the source of trouble.

Circuit Breakers Some circuits are protected by **circuit breakers** (abbreviated c.b. in the fuse chart of a service manual). They can be fuse panel mounted or inline. Like fuses, they are rated in amperes.

Each circuit breaker conducts current through an arm made of two types of metal bonded together (bimetal arm). If the arm starts to carry too much current, it heats up. As one metal expands faster than

Figure 15-49 Cycling circuit breaker.

the other, the arm bends, opening the contacts. Current flow is broken. A circuit breaker can be cycling (**Figure 15-49**) or must be manually reset.

In the cycling type, the bimetal arm begins to cool once the current to it is stopped. Once it returns to its original shape, the contacts are closed and power is restored. If the current is still too high, the cycle of breaking the circuit is repeated.

Two types of noncycling or resettable circuit breakers are used. One is reset by removing the power from the circuit. There is a coil wrapped around a bimetal arm (**Figure 15-50A**). When there is excessive current and the contacts open, a small current passes through the coil. This current through the coil is not enough to operate a load, but it does heat up both the coil and the bimetal arm. This keeps the arm in the open position until power is removed. The other type is reset by depressing a reset button. A spring pushes the bimetal arm down and holds the contacts together (**Figure 15-50B**). When an overcurrent condition exists and the bimetal arm heats up, the bimetal arm bends enough to overcome the spring and the contacts snap open. The contacts stay open until the reset button is pushed, which snaps the contacts together again.

High-Voltage Systems HV systems require special circuit protection devices. Most circuit protection devices used in 12-volt systems are actually rated at 32 volts. If these protection devices were used in a

Figure 15-48 Size comparisons among a standard, mini, and maxi blade fuse.

Figure 15-50 Resetting noncycling circuit breakers by (A) removing power from the circuit and (B) depressing a reset button.

42- or higher volt system, problems such as the burning of the vehicle's wiring and electrical components could result and also cause a fire.

Protection devices for the 42-volt systems are rated at 55 volts. This rating allows protection during times of HV spikes. The protection devices for 42-volt systems, and their receptacles, have a unique design to prevent the installation of the wrong type of fuse.

Higher voltage systems use a variety of electrical and electronic devices to protect the vehicle and circuits. Most have temperature sensors and constantly monitor the current in the system. If the temperature rises above the limit or if the current is higher than normal, the HV system automatically shuts down.

Voltage Limiter Some instrument panel gauges are protected against voltage fluctuations that could damage the gauges or give erroneous readings. A **voltage limiter** restricts voltage to the gauges to a particular amount. The limiter contains a heating coil, a bimetal arm, and a set of contacts. When the ignition is in the on or accessory position, the heating coil heats the bimetal arm, causing it to bend and open the contacts. When the arm cools down to the point that the contacts close, the cycle is repeated. The rapid opening and closing of the contacts produces a pulsating voltage at the output terminal averaging about 5 volts. A voltage limiter is also called an instrument voltage regulator (IVR).

Switches

Electrical circuits are usually controlled by some type of switch (**Figure 15-51**). Switches do two things. They turn the circuit on or off, or they direct the flow of current in a circuit. Switches can be under the control of

Figure 15-51 Examples of the various switches used in automobiles.

the driver or can be self-operating through a condition of the circuit, the vehicle, or the environment.

Contacts in a switch can be of several types, each named for the job they do or the sequence in which they work. A hinged-pawl switch (**Figure 15-52**) is the simplest type of switch. It either makes (allows for) or breaks (opens) current flow in a single conductor or circuit. This type of switch is a **single-pole, single-throw (SPST)** switch. The **throw** refers to the number of output circuits, and the **pole** refers to the number of input circuits made by the switch.

Another type of SPST switch is a momentary contact switch (**Figure 15-53**). The spring-loaded contact on this switch keeps it from closing the circuit except when pressure is applied to the button. A horn switch is this type of switch. Because the spring holds the contacts open, the switch has a further designation: **normally open**. In the case where the contacts are held closed except when the button is pressed, the

Figure 15-52 SPST hinged-pawl switch diagram.

Figure 15-53 SPST momentary contact switch diagram.

Figure 15-54 SPDT headlight dimmer switch.

Figure 15-55 MPMT neutral start safety switch.

switch is designated **normally closed**. A normally closed momentary contact switch is the type of switch used to turn on the courtesy lights when one of the vehicle's doors is opened.

Single-pole, double-throw (SPDT) switches have one wire in and two wires out. **Figure 15-54** shows an SPDT hinged-pawl switch that feeds either the high-beam or low-beam headlight circuit. The dotted lines in the symbol show movement of the switch pawl from one contact to the other.

Switches can be designed with a great number of poles and throws. The transmission neutral start switch shown in **Figure 15-55**, for instance, has two poles and six throws and is referred to as a **multiple-pole, multiple-throw (MPMT)** switch. It contains two movable wipers that move in unison across two sets of terminals. The dotted line shows that the wipers are mechanically linked, or **ganged**. It is important to realize that current does not flow through the mechanical connection of the wipers. The switch closes a circuit to the starter in either P (park) or N (neutral) and to the back-up lights in R (reverse).

Most switches are combinations of hinged-pawl and push-pull switches, with different numbers of poles and throws. Some special switches are required, however, to satisfy the circuits of modern automobiles. A mercury switch is sometimes used to detect motion in a component, such as the one used in the engine compartment to turn on the compartment light.

Mercury is a very good conductor of electricity. In the mercury switch, a capsule is partially filled with mercury (**Figure 15-56**). In one end of the capsule are two electrical contacts. The switch is attached to the

Figure 15-56 A typical mercury switch.

hood or luggage compartment lid. Normally, the mercury is in the end opposite to the contacts. When the lid is opened, the mercury flows to the contact end and provides a circuit between the electrical contacts.

A temperature-sensitive switch usually contains a bimetallic element heated either electrically or by some component in which the switch is used as a **sensor**. When engine coolant is below or at normal operating temperature, the engine coolant temperature sensor is in its normally open condition. If the coolant exceeds the temperature limit, the bimetallic element bends the two contacts together and the switch is closed to the indicator or the instrument panel. Other applications for heat-sensitive switches are time-delay switches and flashers.

Relays

A **relay** is an electric switch that allows a small amount of current to control a high-current circuit (**Figure 15-57**). When the control circuit switch is open, no current flows to the coil of the relay, so the windings are de-energized. When the switch is closed, the coil is energized, turning the soft iron core into an electromagnet and drawing the armature down. This closes the power circuit contacts,

Figure 15-57 The basic way a relay works.

Figure 15-58 A typical electrical relay inner workings and connections. *Courtesy of Chrysler LLC*

Figure 15-59 A solenoid is a device that has a movable electromagnetic core.

connecting power to the load circuit (**Figure 15-58**). When the control switch is opened, current stops flowing in the coil and the electromagnet disappears. This releases the armature, which breaks the power circuit contacts.

Solenoids

Solenoids are also electromagnets with movable cores used to change electrical current flow into mechanical movement (**Figure 15-59**). They are used in a wide variety of systems and can also close contacts, acting as a relay at the same time they mechanically cause something to happen.

Conductors and Insulators

Controlling and routing the flow of electricity requires the use of materials known as conductors and insulators (**Figure 15-60**). **Conductors** are materials that have low resistance to current flow. If the number of electrons in the outer shell or ring of an atom is less than 4, the force holding them in place is weak. The voltage needed to move these electrons and create current flow is relatively small. These are good conductors. Most metals, such as copper, silver, and aluminum, are excellent conductors.

Figure 15-60 Basic construction of a wire.

When the number of electrons in the outer ring is greater than 4, the force holding them in orbit is very strong, and very high voltages are needed to move them. These materials are known as **insulators**. They resist the flow of current. Thermal plastics are the most common electrical insulators used today. They can resist heat, moisture, and corrosion without breaking down. Wire wound inside electrical units, such as ignition coils and generators, usually has a very thin baked-on insulating coating.

WARNING!

Your body is a good conductor of electricity. Remember this when working on a vehicle's electrical system. Always observe all electrical safety rules.

Copper wire is by far the most popular conductor. The resistance of a uniform, circular copper wire depends on the length, the diameter, and the temperature of the wire. If the length is doubled, the resistance between the wire ends is doubled. The longer the wire, the greater the resistance. If the diameter of a wire is doubled, the resistance for any given length is cut in half. The larger the wire's diameter, the lower the resistance.

The other important factor affecting the resistance of a copper wire is temperature. As the temperature increases, the resistance increases. Heat is developed in any wire-carrying current because of the resistance in the wire. If the heat becomes excessive, the insulation will be damaged. Resistance occurs when electrons collide as current flows through the conductor. These collisions cause friction, which in turn generates heat.

Wires Two basic types of wires are used: solid and stranded. **Solid wires** are single-strand conductors. **Stranded wires** are the most common and are made up of a number of small solid wires twisted together to form a single conductor.

Wire size standards were established by the Society of Automotive Engineers (SAE). These standards

are called the **American wire gauge (AWG)** system. Sizes are identified by a numbering system ranging from number 0 to 40, with number 0 being the largest and number 40 the smallest in a cross-sectional area. Most automotive wiring range from number 10 to 24, with battery cables normally 4 gauge or lower. Battery cables must be large gauge wires in order to carry the heavy current draw of the starter motor.

Some manufacturers list wire size in metrics. Metric wiring sizes are based on the cross-sectional area of the wire. Most often wire size is listed in square millimeters (mm²) rather than a metric wire gauge size. The stated size of a metric wire goes up as the wire's diameter increases. This is the opposite of the AWG system. **Table 15-2** gives the closest equivalent size cross references between metric and AWG wire sizes.

Automotive wiring can also be classified as primary or secondary. Primary wiring carries low voltage to all the electrical systems of the vehicle except to the secondary circuit of the ignition system. Secondary wire, also called **high-tension cable**, has extra thick insulation to carry high voltage from the ignition coil to the spark plugs. The conductor itself is designed for low currents.

Wires are commonly grouped together in harnesses. A single-plug harness connector may be the connection for four, six, or more circuits. Harnesses and harness connectors help organize the vehicle's electrical system and provide a convenient starting

Figure 15-61 A typical partial wiring harness that connects to a connector on the fire wall.

point for tracking and testing many circuits. Most major wiring harness connectors are located in a vehicle's dash or fire wall area (**Figure 15-61**).

Flat Wiring As the number of electrical and electronic devices installed in vehicles increases, so does the need for more wiring. More wiring leads to more weight and more potential problems. The size and number of wiring harnesses also increases and spots to carefully tuck them away are limited. For example, a large wiring harness has a difficult time fitting between the roof and the head liner of the vehicle. To run wiring from the front of the vehicle to the rear via the roof, the harnesses are made of small groups of wires, which means there are more harnesses traveling along the roof. Another solution is to make the wiring harnesses flat.

Flat wiring reduces the bulge or thickness of a harness. The copper conductors inside these wires are flattened and no longer round in appearance. In a wiring harness, several flat wires are laid out next to each other and are covered with a plastic insulating material. The plastic offers protection and isolation to the conductors and keeps the harness flat and flexible. In the future, flat wiring may also have electronic components embedded in it. With this design, the wiring harness is not only easier to hide in body panels but also serves as a flexible printed circuit able to be located nearly anywhere in the vehicle.

Printed Circuits Many late-model vehicles use flexible printed circuits (**Figure 15-62**) and printed circuit boards. Both types of printed circuits allow for complete circuits to many components without having to run dozens of wires. Printed circuit boards are typically contained in a housing, such as the engine control module. These boards are not serviceable and in some cases not visible. When these boards fail, the entire unit is replaced.

A flexible printed circuit saves weight and space. It is made of thin sheets of nonconductive plastic onto which conductive metal, such as copper, has been

TABLE 15-2 AWG WIRE GAUGE SIZE

deposited. Parts of the metal are then etched or eaten away by acid. The remaining metal lines form the conductors for the various circuits on the board. The printed circuit is normally connected to the power supply or ground wiring through the use of plug-in connectors mounted on the circuit sheet.

KEY TERMS

Alternating current (AC)	Multiple-pole, multiple throw (MPMT)
American wire gauge (AWG)	Normally closed
Ampere	Normally open
Blade fuse	Ohm
Cartridge fuse	Ohm's law
Ceramic fuse	Open circuit
Chassis ground	Parallel circuit
Circuit breaker	Pole
Closed circuit	Potentiometer
Conductor	Relay
Continuity	Resistance
Current	Resistor wire
Direct current (DC)	Rheostat
Electromotive force (EMF)	Sensor
Electronics	Series circuit
Fixed value resistors	Series-parallel circuit
Fusible link	Sine wave
Ganged	Single-pole, double throw (SPDT)
Ground wire	Single-pole, single throw (SPST)
Grounding	Solid wire
High-tension cable	Spade fuse
High-voltage battery	Starting battery
Impedance	Stepped resistor

SUMMARY

- Electricity results from the flow of electrons from one atom to another.
- The greater the number of electrons flowing past a given point in a given amount of time, the more current the circuit has. The unit for measuring electrical current is the ampere.
- There are two types of current: direct current (DC) and alternating current (AC). In direct current, the electrons flow in one direction only. In alternating current, the electrons change direction at a fixed rate.
- Voltage is electrical pressure or the force developed by the attraction of the electrons to protons.
- Resistance is measured in ohms, which is a measurement of the amount of the resistance something has to current flow.
- A completed electrical circuit is called a closed circuit, whereas an incomplete circuit is called an open circuit. When a circuit is complete, it is said to have continuity.
- The amount of electricity consumed by a load is normally called electrical power usage or watts.
- The mathematical relationship between current, resistance, and voltage is expressed in Ohm's law, $E = IR$.
- Voltage drop is the amount of voltage required to cause current flow through a load.
- Most automotive circuits contain five basic parts: power sources, conductors, loads, controllers, and circuit protection devices.
- There are three basic types of automotive electrical circuits: series circuits, parallel circuits, and series-parallel circuits.
- A series circuit consists of one or more resistors connected to a voltage source with only one path for electron flow.
- A parallel circuit provides two or more different paths for the current to flow through.
- In a series-parallel circuit, both series and parallel combinations exist in the same circuit.
- Resistors limit current flow.
- Fuses, fuse links, maxi-fuses, and circuit breakers protect circuits against overloads.

- Switches control on/off and direct current flow in a circuit.
 - A relay is an electric switch.
 - A solenoid is an electromagnet that translates current flow into mechanical movement.
 - Controlling and routing the flow of electricity requires the use of materials known as conductors and insulators.
 - Two basic types of wires are used: solid and stranded. Solid wires are single-strand conductors. Stranded wires are the most common and are made up of a number of small solid wires twisted together to form a single conductor.
12. What is the current in a 12-volt circuit with two 6-ohm resistors connected in parallel?
 - a. 2 amps
 - b. 4 amps
 - c. 6 amps
 - d. 12 amps
 13. Which of the following does not affect the resistance of a uniform, circular copper wire?
 - a. the length of the wire
 - b. the diameter of the wire
 - c. the location of the wire
 - d. the temperature of the wire
 14. Which of the following is *not* a true statement about maxi-fuses?
 - a. They are used in many late-model vehicles rather than fusible links.
 - b. They automatically reset or can be manually reset and can handle more current than a blade fuse.
 - c. They are normally in their own underhood fuse block.
 - d. They allow the vehicle's electrical system to be broken down into small circuits.
 15. Which of the following technologies is not used to produce electricity in an automobile?
 - a. chemical reactions
 - b. photoelectrical reactions
 - c. thermonuclear reactions
 - d. magnetic induction

REVIEW QUESTIONS

1. What is the name for the formula $E = IR$?
2. *True or False?* In a series circuit, circuit current is the same throughout the circuit.
3. What are the two types of wires and which is the most commonly used in automobiles?
4. Define voltage drop.
5. What is a thermistor?
6. What is a normally closed switch?
7. What happens in an electrical circuit when the resistance increases?
8. What is the difference between voltage and current?
9. What is an SPST switch?
10. Which type of resistor is commonly used in automotive circuits?
 - a. fixed value
 - b. stepped
 - c. variable
 - d. all of the above
11. Which of the following is a characteristic of all parallel circuits?
 - a. Total circuit resistance is always higher than the resistance of the leg with the lowest total resistance.
 - b. The current through each leg will be different if the resistance values are different.
 - c. The sum of the resistance on each leg equals the total circuit resistance.
 - d. The voltage applied to each leg of the circuit will be dropped across the legs if there are loads in series with the parallel circuit.

ASE-STYLE REVIEW QUESTIONS

1. While discussing resistance: Technician A says that current will increase with a decrease in resistance. Technician B says that current will decrease with an increase in resistance. Who is correct?

a. Technician A	c. Both A and B
b. Technician B	d. Neither A nor B
2. Technician A says that a 12-volt light bulb that draws 12 amps has a power output of 1 watt. Technician B says that a motor that has 1 ohm of resistance has a power rating of 144 watts if it is connected to a 12-volt battery. Who is correct?

a. Technician A	c. Both A and B
b. Technician B	d. Neither A nor B

3. While discussing a 12-volt circuit with three resistors (a 3-ohm, a 6-ohm, and a 2-ohm) in parallel: Technician A says that the total resistance of the circuit is 1 ohm. Technician B says that the current flow through the 6-ohm resistor is 12 amps. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
4. While discussing electrical grounds: Technician A says that a component may be grounded through its mounting to a major metal part. Technician B says that some components must be grounded by connecting its positive terminal to a metal section of the frame. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
5. While discussing the batteries in hybrid vehicles: Technician A says that the battery packs must be able to supply bursts of electrical energy. Technician B says that the batteries must be able to accept quick and frequent recharges. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
6. While discussing electrical relays: Technician A says that the relay's coil is energized when the circuit's control switch is open. This action connects power to the load circuit. Technician B says that a relay is an electric switch that allows a large amount of current to control a low-current circuit. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
7. While discussing copper wire: Technician A says that if the length of wire is doubled, the resistance between the wire ends is doubled. Technician B says that if the diameter of a wire is doubled, the resistance between the wire ends is doubled. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
8. While discussing current flow: Technician A says that current results from electrons being attracted to protons. Technician B says that for practical purposes, it is best to remember that current flows from a point of higher potential to a point of lower potential. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
9. While discussing voltage: Technician A says that voltage is the force developed by the attraction of the electrons to protons. Technician B says that the force developed by the attraction of electrons to protons is called electromotive force and it is measured in volts. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
10. While discussing the AWG system: Technician A says that most automotive wiring range from 0 to 4 gauge. Technician B says that the higher the gauge number, the larger the diameter of the wire. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B

GENERAL ELECTRICAL SYSTEM DIAGNOSTICS AND SERVICE

OBJECTIVES

- Describe the different possible types of electrical problems.
- Read electrical automotive diagrams.
- Perform troubleshooting procedures using meters, testlights, and jumper wires.
- Describe how each of the major types of electrical test equipment are connected and interpreted.
- Explain how to use a DMM for diagnosing electrical and electronic systems.
- Explain how to use an oscilloscope for diagnosing electrical and electronic systems.
- Test common electrical components.
- Use wiring diagrams to identify circuits and circuit problems.
- Diagnose common electrical problems.
- Properly repair wiring and connectors.

Diagnosing nearly every system of a vehicle involves electrical and electronic systems. An understanding of how electrical/electronic systems work (**Figure 16-1**) and the knowledge of how to use the various types of test equipment are the keys to efficient diagnosis.

ELECTRICAL PROBLEMS

All electrical problems can be classified into one of three categories: opens, shorts, or high-resistance problems. Identifying the type of problem allows technicians to identify the correct tests to perform when diagnosing an electrical problem. An explanation of the different types of electrical problems follows.

Open Circuits

An **open** occurs when a circuit is incomplete. Without a completed path, current cannot flow (**Figure 16-2**) and the load or component will not work. An open circuit can be caused by a disconnected wire or connector, a broken wire, or a switch in the off position. When a circuit is off, it is open. When the circuit is on, it is closed. Switches open and close circuits, but at times a fault will cause an open. Opening a circuit stops current flow through the circuit. Voltage is still applied up to the open point, but there is no current

flow. Without current flow, there are no voltage drops across the various loads.

Shorted Circuits

When a circuit has an unwanted path for current to follow, it has a **short**. When an energized wire accidentally contacts the frame or body of the car or another wire, circuit current can travel in unintended directions through the wires. This can cause uncontrollable circuits and high current through the circuits. Shorts are caused by damaged wire insulation, loose wires or connections, improper wiring, or careless installation of accessories.

A short creates an unwanted parallel leg or path in a circuit. As a result, circuit resistance decreases and current increases. The amount that the current will increase depends on the resistance of the short. The increased current flow can burn wires or components. Preventing this is the purpose of circuit protection devices. When a circuit protection device opens due to higher than normal current, a short is the likely cause. Also, if a connector or group of wires show signs of burning or insulation melting, high current is the cause, which is most likely caused by a short.

A short can be caused by a number of things and can be evident in a number of ways. It can be an unwanted path to ground. The short is often in

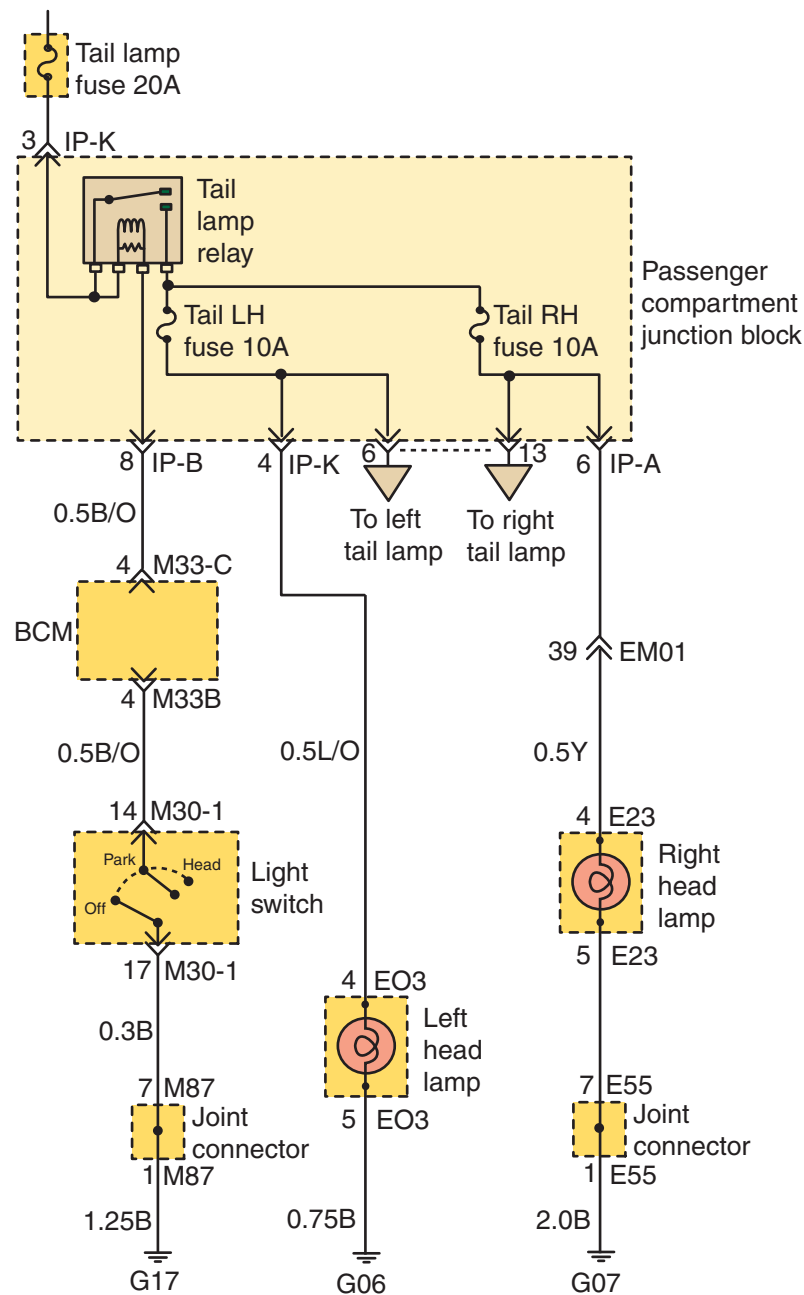

Figure 16-1 A wiring diagram for the tail, parking, and license lamps on a late-model vehicle.

parallel to a load and provides a low-resistance path to ground. Look at **Figure 16-3**; the short is probably caused by bad insulation that is allowing the power feed for the lamp to touch the ground for the same lamp. This problem creates a parallel circuit. **Figure 16-4** represents Figure 16-3 but is drawn to show the short as a parallel leg with very low resistance. The resistance assigned to the short may be more or less than an actual short, but the value 0.001 ohm is given to illustrate what happens. With the short, the circuit has three loads in parallel: 0.001, 3, and 6 ohms. The total resistance of this parallel circuit is less than the lowest resistance or

0.001 ohm. Using this value as the total resistance, circuit current is calculated to be more than 12,000 amps, which is much more than the fuse can handle. The high current will burn the fuse and the circuit will not work. Some call this problem a “grounded circuit” or a “copper-to-iron” short.

Sometimes two separate circuits become shorted together. When this happens, each circuit is controlled by the other. This may result in strange happenings, such as the horn sounding every time the brake pedal is depressed (**Figure 16-5**), or vice versa. In this case, the brake light circuit is shorted to the horn circuit. This is often called a “copper-to-copper” short.

Figure 16-2 In an open circuit, there is no current flow. (A) is a normal circuit, and (B) is the same circuit with an open.

Figure 16-4 Ohm's law applied to Figure 16-3. Notice the rise in circuit amperage.

Figure 16-3 A short to ground.

High-Resistance Circuits

High-resistance problems occur when there is unwanted resistance in the circuit. The higher than normal resistance causes the current flow to be lower than normal and the components in the circuit are unable to operate properly. A common cause of this type of problem is corrosion at a connector. The corrosion becomes an additional load in the circuit (**Figure 16-6**). This load uses some of the circuit's voltage, which prevents full voltage to the normal loads in the circuit.

Many sensors on today's vehicles are fed a 5-volt reference signal. The signal or voltage from the sensor is less than 5 volts depending on the condition it is measuring. A poor ground in the reference voltage circuit can cause higher than normal readings back to the computer. This seems to be contradictory to other

Figure 16-5 A wire-to-wire short.

high-resistance problems. However, if you look at a typical voltage divider circuit used to supply the reference voltage you will understand what is happening. Look at **Figure 16-7**. There are two resistors in series with the voltage reference tap between them. Because the total resistance in the circuit is 12 ohms, the circuit current is 1 amp. Therefore, the voltage drop across the 7-ohm resistor is 7 volts, leaving 5 volts at the tap.

Figure 16-8 is the same circuit, but a bad ground of 1 ohm was added. This low of resistance could be caused by corrosion at the connection. With the bad ground, the total resistance is now 13 ohms. This decreases our circuit current to approximately

Figure 16-6 A simple light circuit with unwanted resistance. Notice the reduced voltage drop across the lamp and the reduced circuit current.

Figure 16-7 A voltage divider circuit.

Figure 16-8 A voltage divider circuit with a bad ground.

0.92 amp. With this lower amperage, the voltage drop across the 7-ohm resistor is now about 6.46 volts, leaving 5.54 volts at the voltage tap. This means the reference voltage would be more than one-half volt higher than it should be. As a result, the computer will be receiving a return signal of at least one-half volt higher than it should. Depending on the sensor and the operating conditions of the vehicle, this could be critical.

ELECTRICAL WIRING DIAGRAMS

Wiring diagrams, sometimes called **schematics**, show how circuits are constructed. A typical service manual contains dozens of wiring diagrams that can be used to diagnose and repair a vehicle's electrical system.

A wiring diagram does not show the actual location of the parts or their appearance, nor does it indicate the length of the wire that runs between

components. It usually indicates the color of the wire's insulation (**Figure 16-9**) and sometimes the wire gauge size. Typically the wire insulation is color coded as shown in **Table 16-1**. The first letter

	Circuit breaker		Connector 101
	Condenser		Male connector
	Ohms		Female connector
	Fixed value resistor		Splice
	Variable resistor		Splice number
	Series resistors		Thermal element
	Coil		Multiple connectors
	Open contacts		Digital readout
	Closed contacts		Single filament bulb
	Closed switch		Dual filament bulb
	Open switch		Light-emitting diode
	Ganged switch (N.O.)		Thermistor
	Single pole double throw switch		PNP bipolar transistor
	Momentary contact switch		NPN bipolar transistor
	Pressure switch		Gauge

Figure 16-10 Common electrical symbols used on wiring diagrams.

or set of letters usually indicates the base color of the insulation. The second set refers to the color of the stripe, hash marks, or dots on the wire, if there are any. Circuits are traced through a vehicle by identifying the beginning and end of a particular colored wire.

Many different symbols are used to represent components such as resistors, batteries, switches, transistors, and many other items. Some of these symbols have already been shown in earlier discussions. Other common symbols are shown in **Figure 16-10**. Connectors, splices, grounds, and other details are also given in a wiring diagram; a sample of these is shown in **Figure 16-11**.

Wiring diagrams can become quite complex. To avoid this, most diagrams usually illustrate one distinct system, such as the back-up light circuit, oil pressure indicator light circuit, or wiper motor circuit. In more complex ignition, electronic fuel injection, and computer-controlled systems, a diagram may be used to illustrate only part of the entire circuit.

USING SERVICE INFORMATION

Electrical symbols are not standardized throughout the automotive industry. Different manufacturers may have different methods of representing certain components, particularly the less common ones. Always refer to the symbol reference charts, wire color code charts, and abbreviation tables listed in the service information to avoid confusion when reading wiring diagrams.

ELECTRICAL TESTING TOOLS

With a basic understanding of electricity and simple circuits it is easier to understand the operation and purpose of the various types of electrical test equipment, which are described in the following sections. Several meters are used to test and diagnose electrical systems. These are the voltmeter, ohmmeter, ammeter, and volt/amp meter. These should be used along with jumper wires, testlights, and variable resistors (piles).

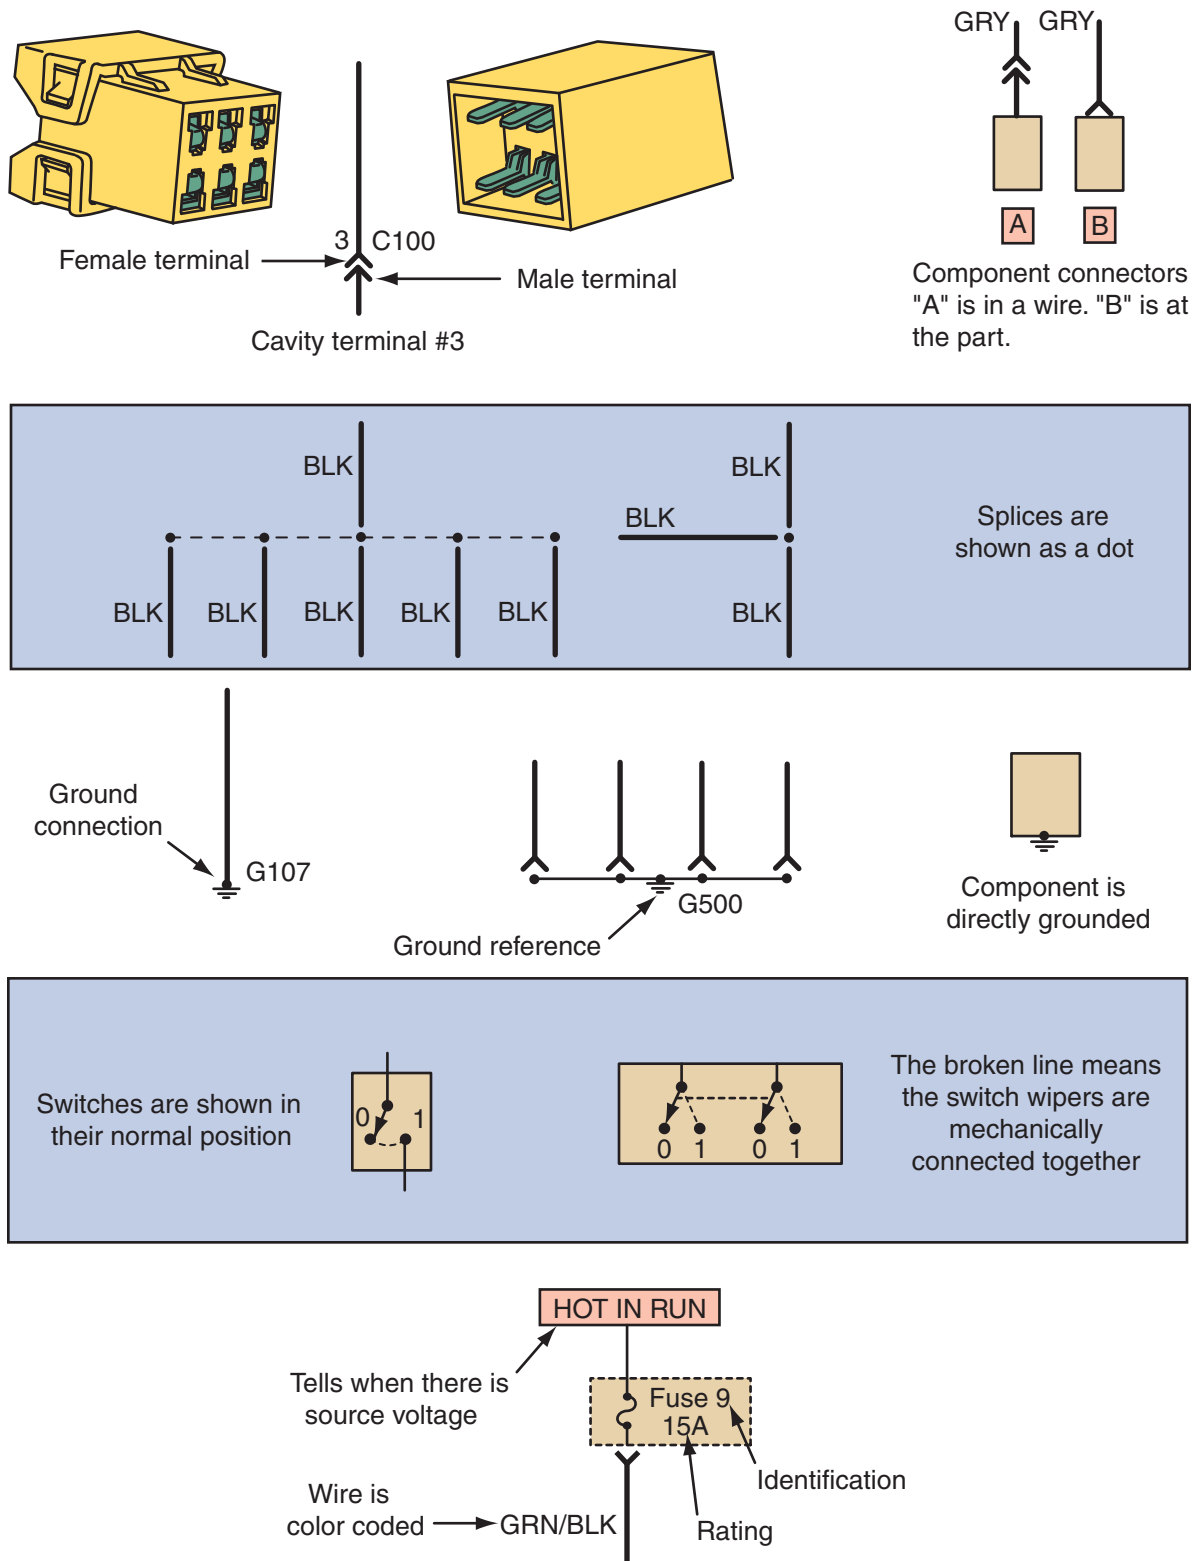

Figure 16-11 Examples of the information contained in a typical wiring diagram (schematic).

Refer to Chapter 5 for a description and basic uses for the various electrical test equipment.

Circuit Testers

Circuit testers (testlights) are used to identify shorted and open circuits in electrical circuits. Low-voltage testers are used to troubleshoot 6- to 12-volt circuits. High-voltage circuit testers diagnose higher voltage systems, such as the secondary ignition circuit.

Figure 16-12 A testlight will illuminate when the probe is touched to part of the circuit that is powered.

High-impedance testlights are available for diagnosing electronic systems.

There are two basic types of testlights: nonpowered and powered. Nonpowered testlights are used to check for available voltage. With the wire lead connected to a good ground and the tester's probe at a point of voltage, the light turns on with the presence of voltage (**Figure 16-12**). The amount of voltage determines the brightness of the light.

A self-powered testlight is used to check for continuity. Hooked across a circuit or component, the light turns on if the circuit is complete. A powered testlight should only be used if the power for the circuit or component has been disconnected.

Multimeter

A multimeter is one of the most important tools for troubleshooting electrical and electronic systems. A basic multimeter measures DC and AC voltage, current, and resistance. A multimeter eliminates the need for separate electrical meters. Most current multimeters also check engine speed, signal frequency, duty cycle, pulse width, diodes, temperature, and pressures. The desired test is selected by turning a control knob or depressing keys on the meter. These meters can be used to test simple electrical circuits, ignition systems, input sensors, fuel injectors, batteries, and starting and charging systems.

Lab Scopes

Lab scopes are fast reacting meters that measure and display voltages within a specific time frame. The voltage readings appear as a waveform or trace on the scope's screen. An upward movement of the trace indicates an increase in voltage, and a decrease in voltage results in a downward movement. These are especially valuable when watching the action of a circuit. The waveform displays what is happening and any problems can be observed when they happen.

Figure 16-13 A typical scan tool.

This gives the technician a chance to observe what caused the change.

Scan Tools

When plugged into the vehicle's diagnostic connector, a scan tool can retrieve fault codes from a computer's memory and digitally display these codes (**Figure 16-13**). A scan tool may also perform other diagnostic functions depending on the year and make of the vehicle. Many scan tools have removable modules that are updated each year. These modules are designed to test the computer systems on various makes of vehicles.

The scan tool must be programmed for the model year, make of vehicle, and type of engine. With some scan tools, this selection is made by pressing the appropriate buttons on the tester as directed by the digital tester display. On other scan tools, the appropriate memory card must be installed in the tester for the vehicle being tested. Some scan tools have a built-in printer to print test results, whereas others may be connected to an external printer.

Some scan tools display diagnostic information based on the trouble code. Service bulletins may also be indexed on the tool after vehicle information is entered into the tester. Other scan tools can also function as a multimeter. After retrieving related trouble codes, the tool allows for detailed testing. Most of these tools will display sensor specifications and instructions for further testing (**Figure 16-14**).

Trouble codes are only set by the vehicle's computer when a voltage signal is entirely out of its normal range. The codes help technicians identify the cause of the problem. If a signal is within its normal range but it is still not correct, the vehicle's computer

Figure 16-14 Some scan tools can also function as a multimeter and may display sensor specifications and instructions for further testing.

will not display a trouble code. However, a problem will still exist. As an aid to identify this type of problem, most manufacturers recommend that the signals to and from the computer be carefully looked at. This is done by observing the serial data stream or through the use of a breakout box.

Other Test Equipment

Other electrical test equipment may be needed to accurately diagnose an electrical circuit.

Jumper Wires Jumper wires are used to bypass individual wires, connectors, or components. Bypassing a component or wire helps to determine if that part is faulty (**Figure 16-15**). If the symptom is no longer evident after the jumper wire is installed, the part bypassed is faulty. Technicians typically

Figure 16-15 A jumper wire can be used to bypass a switch.

have jumper wires of various lengths; usually they have a fuse or circuit breaker in them to protect the circuits being tested.

Computer Memory Saver Whenever a vehicle's battery needs to be disconnected, connect a memory saver to the vehicle. This saver will preserve the memory in the radio, electronic accessories, and the engine, transmission, and body computers.

Two types of memory savers are available or can be made for late-model vehicles. For a power source, use a 12-volt automotive battery or a 12-volt dry-cell lantern battery. If the vehicle's cigar lighter is continuously powered, a cigar lighter adapter plug with suitable wire leads and large alligator clips can be attached to the auxiliary battery. If the cigar lighter is controlled by the ignition switch, a set of jumper wires with alligator clips can be connected to the vehicle's electrical system.

To make either type of saver, use number 14 or 16 wire. Install a 5-ampere inline fuse in the positive lead, along with a diode (**Figure 16-16**). The fuse will protect the memory saver and the electrical system from an accidental short. The diode will prevent current feedback from the vehicle's electrical system to the auxiliary battery.

If you connect the memory saver under the hood, do not connect it to the battery cable clamps. Removing and reinstalling the battery will likely dislodge the memory saver's alligator clips and make it useless. Instead, connect the saver's negative (–) lead to a good engine ground and the positive (+) lead to a point that is hot at all times, such as the battery connection at the generator or starter relay. Check a wiring diagram if you are unsure about the connection points.

If the memory saver must stay connected while the vehicle is raised and lowered on a hoist, securely place the battery out of the way of all moving parts. If

Figure 16-16 A homemade memory saver.

you place the battery inside the car, set it in a large plastic tray or tub to protect the vehicle from electrolyte or battery corrosion.

USING MULTIMETERS

Multimeters are available with either analog or digital displays. Analog meters (**Figure 16-17**) use a needle to point to a value on a scale. A digital meter shows the measured value in numbers or digits. The most commonly used meter is the digital multimeter (DMM), sometimes called a digital volt/ohmmeter (DVOM). Analog meters should not be used to test electronic components. They have low internal resistance (input impedance). The low input impedance allows too much current to flow through circuits and can damage delicate electronic devices. Digital meters, on the other hand, have high input impedance, 1 megohm (million ohms) to 10 megohms. In addition, metered voltage for resistance tests is well below 5 volts, reducing the risk of damage to sensitive components and delicate computer circuits.

SHOP TALK

The DMM used on high-voltage systems in hybrids should be classified as a category III meter. There are basically four categories for electrical meters, each built for specific purposes and to meet certain standards. The categories define how safe a meter is when measuring certain circuits. The standards for the various categories are defined by the American National Standards Institute (ANSI), the International Electrotechnical Commission (IEC), and the Canadian Standards Association (CSA). A CAT III meter is required for testing hybrid vehicles because of the high voltages, three-phase current, and the potential for high transient voltages. Transient voltages are voltage surges or spikes that occur in AC circuits. To be safe, you should have a CAT III 1,000 V meter. Within a particular category, meters have different voltage ratings. These reflect a meter's ability to withstand higher transient voltages. Therefore, a CAT III 1,000 V meter offers much more protection than a CAT III meter rated at 600 volts (**Figure 16-18**).

The front of a DMM is normally comprised of four distinct sections: the display area, range selectors, mode selector, and jacks for the test leads (**Figure 16-19**). In the center of the display are large digits that represent the measured value. Normally there are four to five digits with a decimal point. To

Figure 16-17 An analog multimeter.

Figure 16-18 Only meters with this symbol should be used on the high-voltage systems in a hybrid vehicle; it is preferable that the equipment is rated at 1,000 V.

Figure 16-19 The front of a DMM normally has four distinct sections: the display area, range selectors, mode selector, and jacks for the test leads.

the right of the number, the measured units are displayed (V, A, or Ω). These units may be further defined by a symbol to denote a value of more or less than one. Examples of these are shown in **Figure 16-20**. In the upper-right-hand corner of the display, the type of voltage—AC or DC—is displayed. In the lower-right-hand corner of the display, the

Symbol	Name	Value
mV	millivolts	volts x 0.001
kV	kilovolts	volts x 1,000
mA	milliamps	amps x 0.001
μA*	microamps	amps x 0.000001
kΩ	kilo-ohms	ohms x 1,000
MΩ	megohms	ohms x 1,000,000

*Automotive technicians seldom use readings at the microamp level.

Figure 16-20 Symbols used to define the value of a measurement on a DMM.

DMM displays the measurement range; the range is automatically adjusted by the DMM or manually set by the technician (**Figure 16-21**).

Setting the range on a DMM is important. If the measurement is beyond the set range, the meter will display a reading of “OL” or over limit (**Figure 16-22**). The range on some DMMs is manually set, whereas others have an “auto range” feature, in which the appropriate scale is automatically selected by the

Figure 16-21 The measurement display also shows other important information. Some of this defines the measured value, the type of voltage—AC or DC—and the range selected on the meter.

Figure 16-22 On some DMMs, an infinite reading is displayed as “OL.”

meter. Meters with auto range allow you to disable it when you want to manually select ranges. Auto ranging is helpful when you do not know what value to expect. When using a meter with auto range, make sure you note the range being used by the meter. There is a big difference between 10 ohms and 10,000,000 (10 M) ohms.

WARNING!
*Many DMMs with auto range display the measurement with a decimal point. Make sure you observe the decimal and the range being used by the meter (**Figure 16-23**). A reading of .972 K ohm equals 972 ohms. If you ignore the decimal point you will interpret the reading as 972,000 ohms.*

The mode selector defines what the meter will be measuring (**Figure 16-24**). The number of available modes varies with meter design, but nearly all have the following:

- Volts AC
- Volts DC
- Millivolts (mV) DC
- Resistance/Continuity (ohms)
- Diode Check
- Amps or Milliamps AC/DC

Most DMMs have two test leads and four input jacks. The black test lead always plugs into the COM

0.345 $\text{K}\Omega$ = **345** Ω

1025 mAmps = **1.025** Amps

Figure 16-23 Placement of decimal point and the scale should be noticed when measuring with a meter with auto range.

Figure 16-24 The mode selector defines what the meter will be measuring.

input jack and the red lead plugs into one of the other input jacks, depending on what is being measured. Often technicians have multiple sets of test leads, each for specific purposes. For example, a lead set with small tips is ideal for probing in hard-to-reach or tight spaces. Other test leads may be fitted with clips to hold the lead at a point during testing.

Typically, the three input jacks are:

- “A” for measuring up to 10 amps of current
- “A/mA” for measuring up to 400 mA of current
- “V/ Ω /diode” for measuring voltage, resistance, conductance, capacitance, and checking diodes

Measuring Voltage

A DMM can measure source voltage, available voltage (Figure 16-25), and voltage drops. Voltage is measured by placing the meter in parallel to the component or circuit being tested (Figure 16-26). There are normally several voltage ranges available on a DMM. Most automotive circuits range from 50 mV to 15 volts.

Figure 16-25 Checking available voltage at points within a circuit with a voltmeter.

WARNING!

Hybrid vehicles have much higher voltage; always follow all safety precautions and service procedures when working with high-voltage circuits.

A DMM can be used to check for proper circuit grounding. For example, if the voltmeter shows battery voltage at a lamp but no lighting is seen, the bulb

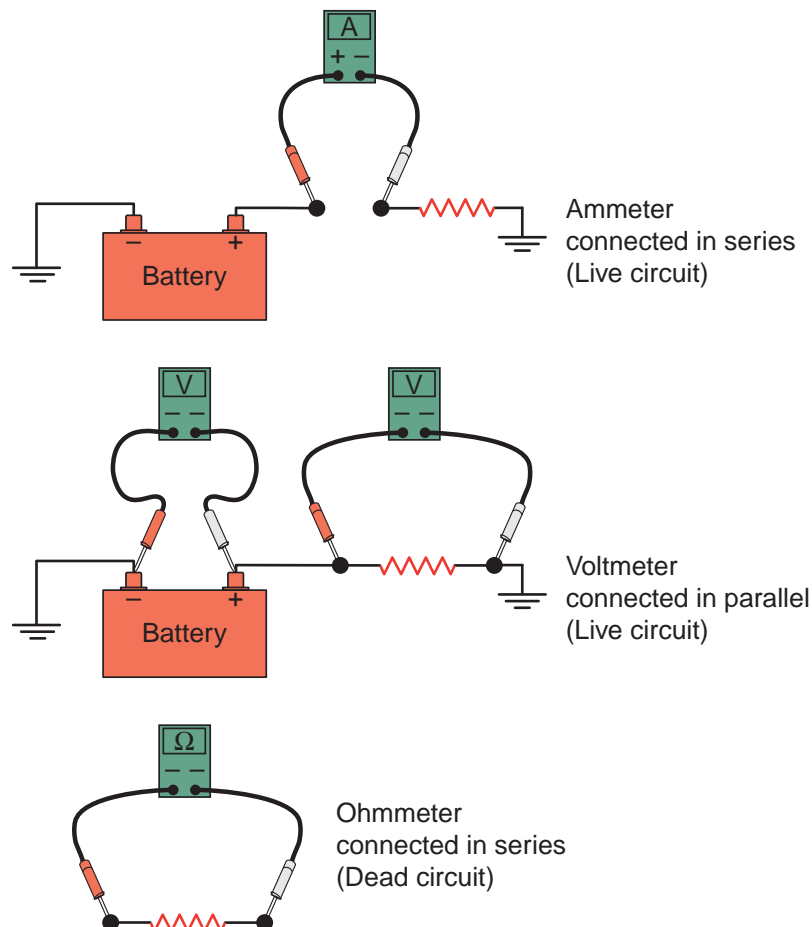

Figure 16-26 A voltmeter is connected in parallel or across a component or part of a circuit to measure available voltage and voltage drop.

Figure 16-27 Using a voltmeter to check for open grounds.

or socket could be bad or the ground connection is faulty. An easy way to check for a defective bulb is to replace it with one known to be good. You can also use an ohmmeter to check for electrical continuity through the bulb.

If the bulbs are not defective, the problem is the light sockets or ground wires. Connect the voltmeter to the ground wire and a good ground as shown in **Figure 16-27**. If 0 volts is measured, move the positive meter lead to the power feed side of the bulb. If 0 volts is measured there, the light socket or feed wire is defective. In a normal light circuit, there should be 0 volts at the negative side of the bulb. If the socket is not defective and some voltage is measured at the ground, the ground circuit is faulty. The higher the voltage, the greater the problem.

PROCEDURE

To measure DC voltage:

1. Set the mode selector switch to Volts DC.
2. Select the auto range function, or manually set the range to match the anticipated value; normally the range is set to the closest to and higher than 12 volts.
3. Connect the test leads in parallel to the circuit or component being tested. The red lead should be connected first to the most positive side (side closest to the battery). The black lead is connected to a good ground.
4. Read the measurement on the display. If the reading is negative, it is likely that the leads are reversed.

Voltage Drop Test Measuring voltage drop is a very important test. It can identify circuits with unwanted resistances. This test is extremely valuable when working with electronic circuits; even the smallest loss of voltage will affect the performance of parts and

Figure 16-28 Measuring the voltage drop across the battery post and cable. It is easy to see why the voltage drop is high!

the vehicle as a whole. The test can be performed between any two points in a circuit and across any component, such as wires, switches, relay contacts and coils, and connectors (**Figure 16-28**). A voltage drop test can find excessive resistance in a circuit that may not be detected using an ohmmeter. An ohmmeter works by passing a small amount of current through the component being tested while it is isolated from the circuit. A voltage drop test is conducted with the circuit operating with normal amounts of current.

Consider a simple circuit. If there are 12 volts available at the battery and the switch is closed, there should also be 12 volts available at each light. If, for example, less than 12 volts are measured, that means some additional resistance is somewhere else in the circuit. The lights may light but not as brightly as they should.

Figure 16-29 illustrates two headlights (2 ohms each) connected to a 12-volt battery using two wires. Each wire has an unwanted resistance of 0.05 ohm.

Figure 16-29 Wire resistance results in a slight voltage drop in the circuit.

The two headlights are wired parallel, and total resistance of the headlights is:

$$\frac{2 \text{ ohms} + 2 \text{ ohms}}{2 \text{ ohms} + 2 \text{ ohms}} = 1 \text{ ohm}$$

The total circuit resistance is:

$$1 \text{ ohm} + 0.05 \text{ ohm} + 0.05 \text{ ohm} = 1.1 \text{ ohms}$$

Therefore, the current in the circuit is

$$I = \frac{E}{R} = \frac{12}{1.1} = 10.9 \text{ amperes}$$

The voltage drop across each wire is:

$$E = I \div R$$

$$E = 10.9 \div 0.05 = 0.54 \text{ V}$$

This means there is a total of 1.08 volts dropped across the wires. When the voltage drop of the wires is subtracted from the 12-volt source voltage, 10.92 volts remain for the headlights.

Without the resistance in the wires, the headlights receive 12 amperes. With the resistance, the current flow was reduced to 10.9 amperes. The decreased current and voltage drop means the lights will not be as bright as normal.

PROCEDURE

The procedure for measuring voltage drop is shown in Photo Sequence 12. To measure voltage drop:

1. Set the DMM to the mV or V DC mode.
2. Set the DMM to auto range or a low-voltage range.
3. Connect the positive test lead to the most positive side of the part or circuit being tested.
4. Connect the negative test lead to the least positive side of the part or circuit being tested.
5. Power the circuit. Current must be flowing in order to have a voltage drop.
6. Read the meter. Excessive voltage drops indicate excessive resistance (an unwanted load) in that portion of the circuit.

Voltage drops should not exceed the following:

- 200 mV across a wire or connector
- 300 mV across a switch or relay contacts
- 100 mV at a ground connection
- 0 mV to < 50 mV across all sensor connections

Measuring AC Voltage There are two ways that multimeters display AC voltage: **root mean square (RMS)** and **average responding**. When an AC voltage signal is a true sine wave, both methods will display the same reading. Because most automotive sensors do not produce pure sine wave signals, it is important to know how the meter will display the AC voltage reading when comparing measured voltage to specifications. RMS meters convert the AC signal to a comparable DC voltage signal. Average responding meters display the average voltage peak. Always check the voltage specification to see if the specification is for RMS voltage; if it is, use an RMS meter (**Figure 16-30**).

Measuring Current

Testing the current through a circuit gives a true picture of what is happening in the circuit. This is because the circuit is being tested under load. Low current indicates that the circuit has higher than normal resistance, and high current means the circuit has lower than normal resistance. Many technicians do not check current because few specifications list what should be normal. This should not be a problem because current can be calculated if you know the resistance and voltage in the circuit. Remember, to have current the circuit must be complete and there must be voltage applied to it.

The circuit in **Figure 16-31** normally draws 6 amps and is protected by a 10 amp fuse. If the circuit constantly blows the fuse, a short exists somewhere in the circuit. Mathematically, each light should draw 1.5 amperes ($6 \div 4 = 1.5$). To find the short, disconnect all lights by removing them from their sockets. Then, close the switch and read the ammeter. With

Figure 16-30 AC voltage: RMS.

Performing a Voltage Drop Test

P12-1 Tools required to perform this task: voltmeter and fender covers.

P12-2 Set the voltmeter on its lowest DC volt scale.

P12-3 To test the voltage drop of the entire headlamp system, connect the positive (red) lead to the battery positive terminal.

P12-4 Connect the negative (black) lead to the low beam terminal of the headlight socket. Make sure you are connected to the battery "+" or power feed wire of the headlight.

P12-5 Turn on the headlights (low beam) and look at the voltmeter reading. The voltmeter will show the amount of voltage dropped between the battery and the headlight. This reading should be very low.

Figure 16-31 Checking a circuit using an ammeter.

the loads disconnected, the meter should read 0 ampere. If there is any reading, the wire between the fuse and the sockets is shorted to ground.

If 0 amp was measured, reconnect each light in sequence; the reading should increase 1.5 amperes with each bulb. If, when making any connection, the reading is higher than expected, the problem is in that part of the light circuit.

WARNING!

When testing for a short, always use a fuse. Never bypass the fuse with a wire. The fuse should be rated at no more than 50% higher capacity than specifications. This offers circuit protection and provides enough amperage for testing. After the problem is found and corrected, be sure to install a fuse with the specified rating.

Before checking current, make sure the meter is capable of measuring the suspected amount. To check the rating of the meter, look at the rating printed next to the DMM input jacks or check the rating of the meter's fuse (maximum current capacity is typically the same as the fuse rating). If you suspect that a measurement will have a current higher than the meter's maximum rating, use an inductive current probe.

An ammeter must be connected in series with the circuit; this allows circuit current to flow through the meter.

PROCEDURE

To measure current:

1. Turn off the circuit that will be tested.
2. Connect the test leads to the correct input jacks on the DMM.
3. Set the mode selector to the correct current setting (normally amps or milliamps).

4. Select the auto range function, or manually select the range for the expected current.
5. Open the circuit at a point where the meter can be inserted.
6. Connect a fused jumper wire to one of the test leads.
7. Connect the red lead to the most positive side of the circuit and the black lead to the other side.
8. Turn on the circuit.
9. Read the display on the DMM.
10. Compare the reading to specifications or your calculations.

WARNING!

Never place the leads of an ammeter across the battery or a load. This puts the meter in parallel with the circuit and will blow the fuse in the ammeter or possibly destroy the meter.

Inductive Current Probes Many DMMs have current probes (current clamps) that eliminate the need to insert the ammeter into the circuit. These probes read current by sensing the magnetic field formed in a wire by current flow (**Figure 16-32**). Normally, to use a current probe, the DMM's mode selector is set to read millivolts (mV). The probe is then connected to the meter and turned on. Some probes must be zeroed prior to taking a measurement. This is done before the probe is clamped around a wire. The DMM may have a zero adjust control, which is turned until zero reads on the meter's display. The clamp is placed around a wire in the circuit being tested (**Figure 16-33**). Make sure the arrow on the clamp is pointing in the direction of current flow. After the clamp is in place, the circuit is turned on and the

Figure 16-32 A low-amp current probe. Courtesy of SPX Service Solutions

Figure 16-33 A current probe attached to a DMM allows for current measurements without breaking the circuit.

voltage read on the display. The voltage reading is then converted to an amperage reading—1 mV = 1 ampere.

Measuring Resistance

DMMs are used to test circuit continuity and resistance with no power applied. In other words, the circuit or component must first be disconnected from the power source (**Figure 16-34**). Connecting an ohmmeter into a live circuit usually results in damage to the meter.

Checking the resistance can be used to check the condition of a component (**Figure 16-35**) or circuit. Often specifications list a normal range of resistance values for specific parts. If the resistance is too high, check for an open circuit or a faulty component. Excessive resistance can prevent a circuit from operating normally. Loose, damaged, or dirty connections are common causes of excessive resistance. If the resistance is too low, check for a shorted circuit or faulty component.

Figure 16-34 Measuring resistance using an ohmmeter. Note that the circuit fuse is removed to de-energize the circuit.

Figure 16-35 An ohmmeter can test the resistance of a component after it has been removed from the circuit.

CAUTION!

To avoid possible damage to the meter or to the equipment under test, disconnect the circuit power and discharge all high-voltage capacitors before measuring resistance. Always follow the manufacturer's test procedures when testing air bags.

Ohmmeters also are used to trace and check wires or cables. Connect one probe of the ohmmeter to the known wire at one end of the cable and touch the other probe to each wire at the other end of the cable. Any evidence of resistance indicates the correct wire. Using this same method, you can check for a defective wire. If low resistance is shown on the meter, the wire is sound. If no resistance is measured, the wire is open. Any indication of resistance means the wire may be shorted to another wire and the harness is defective.

PROCEDURE

To measure resistance:

1. Make sure the circuit or component to be tested is not connected to any power source.
2. Set the DMM mode selector to measure resistance.
3. Select the auto range feature or manually select the appropriate range.

4. Calibrate the meter by holding the two test leads together and adjusting the meter to zero. On some DMMs, the calibration should be checked whenever the range is changed.
5. Connect the meter leads in parallel to the component or part of the circuit that will be checked.
6. Read the measured value on the display. The DMM will show a zero or close to zero when there is good continuity. If there is no continuity, the meter will display an infinite or over-limit reading.

Continuity Tests Many DMMs have a continuity test mode that makes a beeping noise when there is continuity through the item being tested. This audible sound will continue as long as there is continuity. This feature can be handy for finding the cause of an intermittent problem. By connecting the DMM across a circuit and wiggling sections of the wiring harness, a problem can be noted when the beeping stops after a particular section or wire has been moved.

MIN/MAX Readings

Some DMMs also feature a MIN/MAX function. This displays the maximum, minimum, and average voltage recorded during the time of the test. This is valuable when checking sensors or when looking for electrical noise. Noise is primarily caused by radio frequency interference (RFI), which may come from the ignition system. RFI is an unwanted voltage signal that rides on a signal. This noise can cause intermittent problems with unpredictable results. The noise causes slight increases and decreases in the voltage. When a computer receives a voltage signal with noise, it will try to react to the minute changes. As a result, the computer responds to the noise rather than the voltage signal.

Other Measurements

Multimeters may also have the ability to measure duty cycle, pulse width, and frequency. Duty cycle (Figure 16-36) is measured as a percentage. A 60%

duty cycle means that a device is on 60% of the time and off 40% of one cycle. When measuring duty cycle, you are looking at the amount of time something is on during one cycle.

Pulse width is normally measured in milliseconds. When measuring pulse width, you are looking at the amount of time something is on.

To accurately measure duty cycle, pulse width, and frequency, the meter's trigger level must be set. The trigger level tells the meter when to start counting. Trigger levels can be set at certain voltage levels or at a rise or fall in the voltage. Normally, meters have a built-in trigger level that corresponds with the voltage range setting. If the voltage does not reach the trigger level, the meter will not begin to recognize a cycle. On some meters you can select between a rise or fall in voltage to trigger the cycle count. Most technicians refer to this as a positive or negative slope trigger. A rise in voltage is a positive increase in voltage. This setting is used to monitor the activity of devices whose power feed is controlled by a computer. A fall in voltage is negative voltage. This setting is used to monitor ground-controlled devices.

Some DMMs can measure temperature. These meters are equipped with a thermocouple. Temperature readings can be made in Fahrenheit or Celsius. The thermocouple is connected to the DMM and placed on or near the object to be checked.

More elaborate DMMs have the ability to store and download data to a PC.

Safety Guidelines

To avoid possible electric shock or personal injury while using a DMM, follow these guidelines:

- Use a meter only as it was designed to be used; misuse may defeat the protection devices built into the meter.
- Never use a damaged meter.
- Make sure the battery is secure and totally enclosed with the meter.

Figure 16-36 Duty cycle is expressed in a percentage.

- Inspect the test leads for damaged insulation or exposed metal. Replace damaged test leads before you use a meter.
- Never apply more than the rated voltage of the meter between the terminals or between any terminal and ground.
- Be extra careful when measuring high voltages.
- Use the proper connections, terminals, mode, and range for the measurements being taken.
- When measuring current, turn off the power to the circuit before connecting the meter in series with the circuit.
- When making electrical connections, connect the negative test lead before connecting the positive test lead; when disconnecting, disconnect the positive test lead before disconnecting the negative test lead.
- When using probes, keep your fingers behind the finger guards on the probes.
- Disconnect the power to the circuit and discharge all high-voltage capacitors before testing resistance, continuity, diodes, or capacitance.
- When testing HV components or circuits, wear high-voltage lineman's gloves.

USING LAB SCOPES

The lab scope has become the diagnostic tool of choice for many good technicians. When measuring voltage with an analog voltmeter, the meter only displays the average values at the point being probed. Digital voltmeters simply sample the voltage several times each second and update the meter's reading at a particular rate. If the voltage is constant, good measurements can be made with both types of voltmeters. A scope, however, will display any change in voltage as it occurs. This is important for diagnosing intermittent problems.

The screen is divided into small divisions of time and voltage (**Figure 16-37**). These divisions set up a grid pattern on the screen. Time is represented by the horizontal movement of the trace. Voltage is measured with the vertical position of the trace. Because the scope displays voltage over time, the trace moves from the left (the beginning of measured time) to the right (the end of measured time). The value of the divisions can be adjusted to improve the view of the voltage trace. For example, the vertical scale can be adjusted so that each division represents 0.5 volt, and the horizontal scale can be adjusted so that each division equals 0.005 second (5 milliseconds). This allows for

Figure 16-37 Grids on a scope screen that serve as a time and voltage reference.

viewing small changes in voltage that occur during a very short period. The grid serves as a reference for measurements.

Because a scope displays actual voltage, it will display any electrical noise or disturbances that accompany the voltage signal (**Figure 16-38**). Electrical disturbances or **glitches** are momentary changes in the signal. These can be caused by intermittent shorts to ground, shorts to power, or opens in the circuit. These problems can occur for only a moment or may last for some time. A lab scope is handy for finding these and other causes of intermittent problems. By observing a voltage signal and wiggling or pulling a wiring harness, any looseness can be detected by a change in the voltage signal.

Figure 16-38 RFI noise and glitches may appear on a voltage signal.

Analog versus Digital Scopes

Analog scopes show the actual activity of a circuit and are called real-time scopes. This simply means that what is taking place at that time is what you see on the screen. Analog scopes have a fast update rate that allows for the display of activity without delay.

A digital scope, commonly called a **digital storage oscilloscope** or **DSO**, converts the voltage signal into digital information and stores it into its memory. Some DSOs send the signal directly to a computer or a printer or save it to a disk. To help in diagnostics, a technician can “freeze” the captured signal for close analysis. DSOs also have the ability to capture low-frequency signals. Low-frequency signals tend to flicker when displayed on an analog screen. To have a clean waveform on an analog scope, the signal must be repetitive and occurring in real time. The signal on a DSO is not quite real time. Rather it displays the signal as it occurred a short time before.

This delay is actually very slight. Most DSOs have a sampling rate of one million samples per second. This is quick enough to serve as an excellent diagnostic tool. This fast sampling rate allows slight changes in voltage to be observed. Slight and quick voltage changes cannot be observed on an analog scope.

Because digital signals are based on binary numbers, the trace appears to be slightly choppy when compared to an analog trace. However, the voltage signal is sampled more often, which results in a more accurate waveform. The waveform is constantly being refreshed as the signal is pulled from the scope’s memory.

Both an analog and a digital scope can be dual trace (**Figure 16-39**) or multiple trace (**Figure 16-40**) scopes. This means they have the capability of displaying more than one trace at one time. By watching the traces simultaneously, the cause and effect of a

Figure 16-39 Two or more different signals can be observed on a multiple-channel scope. This is invaluable for diagnosis.

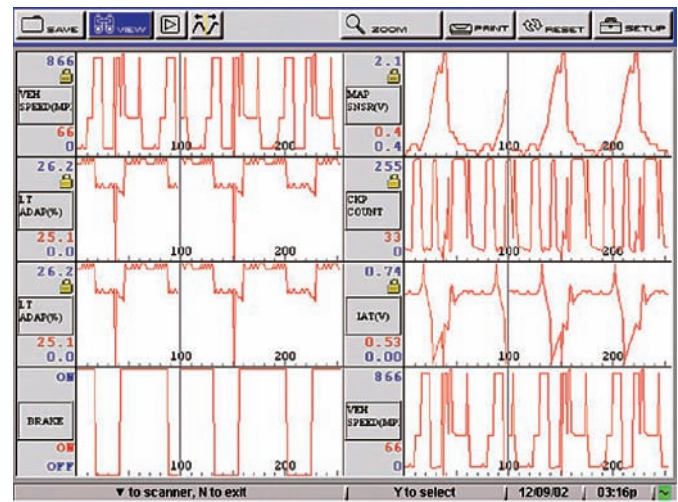

Figure 16-40 Some scopes and graphing scan tools can display many channels. Reproduced under license from Snap-on Incorporated. All of the marks are marks of their owners.

sensor is observed and a good or normal waveform can be compared to the one being displayed.

Waveforms

A waveform represents voltage over time. Any change in the amplitude of the trace indicates a change in the voltage. When the trace is a straight horizontal line, the voltage is constant. A diagonal line up or down represents a gradual increase or decrease in voltage. A sudden rise or fall in the trace indicates a sudden change in voltage.

Scopes can display AC and DC voltage, either one at a time or both at the same time, as in the case of noise caused by RFI. Noise results from AC voltage riding on a DC voltage signal. The consistent change of polarity and amplitude of the AC signal causes slight changes in the DC voltage signal. A normal AC signal changes its polarity and amplitude over time. The waveform created by AC voltage is typically called a sine wave (**Figure 16-41**). One complete sine wave shows the voltage moving from zero to its positive peak then moving down through zero to its negative peak and returning to zero.

One complete sine wave is a cycle. The number of cycles that occur per second is the frequency of the signal. Frequency is measured in cycles per second (hertz or Hz). Checking frequency is one way of checking the operation of some electrical components. Input sensors are the most common components that produce AC voltage. Permanent magnet voltage generators produce an AC voltage that can be checked on a scope (**Figure 16-42**). AC voltage waveforms should also be checked for noise and glitches. These may send false information to the computer.

Figure 16-41 An AC voltage sine wave.

Figure 16-43 A typical square (on-off or high-low) wave.

Figure 16-42 An AC voltage trace from a typical permanent magnet generator-type pickup or sensor.

DC voltage waveforms may appear as a straight line or line showing a change in voltage. Sometimes a DC voltage waveform will appear as a square wave that shows voltage making an immediate change (Figure 16-43). Square waves are identified by having straight vertical sides and a flat top. This type of wave represents voltage being applied (circuit being turned on), voltage being maintained (circuit remaining on), and no voltage applied (circuit is turned off). Of course, a DC voltage waveform may also show gradual voltage changes.

Scope Controls

Depending on manufacturer and model of the scope, the type and number of its controls will vary. However, nearly all scopes have intensity, vertical (Y-axis) adjustments, horizontal (X-axis) adjustments, and trigger adjustments. The intensity control is used to adjust

Figure 16-44 Vertical divisions represent voltage.

the brightness of the trace. This allows for clear viewing regardless of the light around the scope screen.

The vertical adjustment actually controls the voltage that will be shown per division (Figure 16-44). If the scope is set at 0.5 (500 milli) volt, a 5-volt signal will need 10 divisions. Likewise, if the scope is set to 1 volt, 5 volts will need only 5 divisions. While using a scope, it is important to set the vertical so that voltage can be accurately read. Setting the voltage too low may cause the waveform to move off the screen, whereas setting it too high may cause the trace to be flat and unreadable. The vertical position control allows the vertical position of the trace to be moved anywhere on the screen.

The horizontal position control allows the horizontal position of the trace to be set. The horizontal control is actually the time control of the trace (Figure 16-45). If the time per division is set too low, the complete trace may not show across the screen. Also, if the time per division is set too high, the trace may be too crowded for detailed observation. The time

Figure 16-45 Horizontal divisions represent time.

per division (TIME/DIV) can be set from very short periods (millionths of a second) to full seconds.

Trigger controls tell the scope when to begin a trace across the screen. Setting the trigger is important when trying to observe the timing of something. Proper triggering will allow the trace to repeatedly begin and end at the same points on the screen. There are typically numerous trigger controls on a scope. The trigger mode selector has a NORM and an AUTO position. In the NORM setting, no trace will appear on the screen until a voltage signal occurs within the set time base. The AUTO setting will display a trace regardless of the time base.

Slope and level controls are used to define the actual trigger voltage. The slope switch determines whether the trace will begin on a rising or falling of the signal (**Figure 16-46**). The level control sets when the time base will be triggered according to a certain point on the slope.

Figure 16-46 The trigger can be set to start the trace with a rise or fall of voltage.

A trigger source switch tells the scope which input signal to trigger on. This can be Channel 1, Channel 2, line voltage, or an external signal. External signal triggering is very useful when observing the trace of a component that may be affected by the operation of another component. An example of this would be observing fuel injector activity when changes in throttle position are made. The external trigger would be voltage changes at the Throttle Position Sensor. The displayed trace would be the cycling of a fuel injector.

Graphing Multimeters

One of the latest trends in diagnostic tools is a **graphing multimeter (GMM)**. A GMM is a DMM that displays voltage, resistance, current, and frequency as a waveform. The display shows the minimum and maximum readings as a graph, as well as all current measurements (**Figure 16-47**). By observing the graph, a technician can see any undesirable changes during the transition from a low reading to a high reading, or vice versa. These glitches are some of the more difficult problems to identify without a graphing meter or a lab scope. The waveform on a DSO may miss a change in voltage, resistance, or current that occurs too quickly for the scope to detect and display it. DSOs do not display real-time data. There is always a slight delay between what it measures and what it displays, and depending on the refresh rate of the display it may miss some changes completely. A GMM is perhaps the best tool to use when trying to find the cause of intermittent problems in low-voltage DC circuits.

The capabilities of a GMM depend on the manufacturer and the model. Some of the features found on GMMs include a signal and data recorder, individual component tests, the ability to display measurements along with a graph, glitch capture, and an audible alarm. Some also have an electronic library of

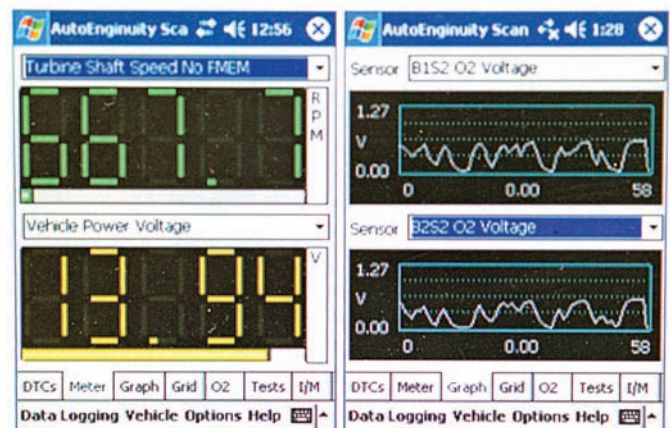

Figure 16-47 A sample of the information available from a GMM.

Figure 16-48 Many scan tools, DSOs, and GMMs allow for the transfer of captured information to a PC through a cable or wireless interface.

known good signals for comparison. These allow for a comparison of live patterns with expected values or known good waveforms. Some even have wiring diagrams and a vehicle-specific database of diagnostic and test information.

Transferring Data to a PC Many DSOs and GMMs allow for the transfer of captured information to a PC through a cable (**Figure 16-48**) or wireless interface. This feature allows for better viewing of the waveforms and other data and also allows for the creation of a personal library. The latter can be helpful in the future. There are several sources of waveforms readily available for download to a PC; these can be used as references and study guides.

TESTING BASIC ELECTRICAL COMPONENTS

All electrical components can fail. Testing them is the best way of determining if they are good or bad. For the most part, the proper way for checking electrical

components is determined by what the component is supposed to do. If we think about what something is supposed to do, we can figure out how to test it. Often, removing the component and testing it on a bench is the best way to check it.

Protection Devices

When overloads or shorts in a circuit cause too much current, the wiring in the circuit heats up, the insulation melts, and a fire can result unless the circuit has some kind of protective device. Fuses, fuse links, maxi-fuses, and circuit breakers are designed to provide protection from high current. They may be used singularly or in combination.

WARNING!

Fuses and other protection devices normally do not wear out. They go bad because something went wrong. Never replace a fuse or fusible link, or reset a circuit breaker, without finding out why they went bad.

Circuit protection devices can be checked with an ohmmeter or testlight. If the fuse is good, there will be continuity through it. To test a circuit protection device with a voltmeter, check for available voltage at both terminals of the unit (**Figure 16-49**). If the device is good, voltage will be present on both sides. A testlight can be used in place of a voltmeter.

Measuring voltage drop across a fuse or other circuit protection device tells more about its condition than its continuity. If a fuse, a fuse link, or a circuit breaker is in good condition, a voltage drop of zero will be measured. If 12 volts is read, the fuse is open. Any reading between 0 and 12 volts indicates that there is unwanted resistance and the fuse should be

Figure 16-49 Circuit protection devices can be tested with a voltmeter. Make sure there is voltage present on both sides of the device.

Figure 16-50 The condition of a fuse can often be checked visually.

replaced. Make sure you check the fuse holder for resistance as well.

Fuses A cartridge fuse can be visually checked by looking at the internal metal strip. Discoloration of the glass cover or glue bubbling around the metal end caps is an indication of overheating. Pull the fuse from its holder and look at the element through the transparent plastic housing. Look for internal breaks and discoloration (**Figure 16-50**). A ceramic fuse is checked by looking for a break in the contact strip on the outside of the fuse.

Sometimes it is necessary to protect a device in a portion of a circuit even though the entire circuit is already protected by a fuse in the panel. This is done by installing an **inline fuse** in the power wire for the device. Inline fuses are primarily used on accessories that are very sensitive to power surges, such as radios and compact disk players. They are also used with driving lights and power antennas.

SHOP TALK

To calculate the correct fuse rating, use Watt's law: watts divided by volts equals amperes. For example, if you are installing a 55-watt pair of fog lights, divide 55 by the battery voltage to find how much current the circuit will draw. In this case, the current is approximately 5 amperes. To allow for current surges, the correct inline fuse should be rated slightly higher than the normal current flow. In this case, an 8- or 10-ampere fuse would do the job.

Fuse Links Fuse link wire is covered with a special insulation that bubbles when it overheats, indicating that the link has melted. If the insulation appears good, pull lightly on the wire. If the link stretches, the wire has melted. Of course, when it is hard to determine if the fuse link is burned out, check for continuity through the link with a testlight or ohmmeter.

WARNING!

Do not mistake a resistor wire for a fuse link. A resistor wire is generally longer and is clearly marked "Resistor do not cut or splice."

To replace a fuse link, cut the protected wire where it is connected to the fuse link. Then tightly crimp or solder a new fusible link of the same rating as the original link.

WARNING!

Always disconnect the battery ground cable prior to servicing any fuse link.

Maxi-Fuses Maxi-fuses are easier to inspect and replace than fuse links. To check a maxi-fuse, look at the fuse element through the transparent plastic housing. If there is a break in the element, it has blown. To replace it, pull it from its fuse box or panel. Always replace a blown maxi-fuse with one that has the same ampere rating.

Circuit Breakers Two types of circuit breakers are used. One is reset by removing the power from the circuit. The other type is reset by depressing a reset button. If a circuit breaker cannot be reset and remains open, replace it after making sure that there is not excessive current in the circuit.

Thermistors Some systems use a positive temperature coefficient (PTC) thermistor as a protection device. When there is high current, the resistance of the thermistor increases and causes a decrease in current flow. These can be checked with an ohmmeter (**Figure 16-51**). If an infinite reading is displayed, the thermistor is open. Another way of checking a thermistor is to change its temperature and see if its resistance changes. A negative temperature coefficient thermistor works in the opposite way; that is, its resistance decreases as the temperature increases.

Switches

To check a switch, disconnect the connector at the switch. Check for continuity between the terminals of the switch (**Figure 16-52**) with the switch in the on and off positions. While in the off position, there should be no continuity between the terminals. With the switch on, there should be good continuity between

Figure 16-51 A temperature sensor (thermistor) can be checked with an ohmmeter.

Figure 16-52 Checking a switch with an ohmmeter.

the terminals. If the switch is activated by something mechanical and does not complete the circuit when it should, check the adjustment of the switch (some switches are not adjustable). If the adjustment is correct, replace the switch. Another way to check a switch is to bypass it with a jumper wire. If the component works when the switch is jumped, the switch is bad. MPMT switches should be checked in each of its possible positions (**Figure 16-53**). Use a wiring diagram to identify which terminals of the switch should have continuity during each switch position.

Voltage drop across switches should also be checked. Ideally when the switch is closed there should be no voltage drop. Excessive voltage drop indicates resistance, and the switch should be replaced.

Relays

A relay can be checked with a jumper wire, a voltmeter, an ohmmeter, or a testlight. If the terminals are accessible and the relay is *not* controlled by a computer, a jumper wire and testlight will be the quickest method to use. The schematic for a relay is typically shown on the outside of the relay. If not, check a wiring diagram to identify the terminals of the relay (**Figure 16-54**). Also check the wiring diagram to determine if the relay is controlled by a power or ground switch.

Figure 16-53 An MPMT switch should be checked in all of its possible positions. Use a wiring diagram to guide your tests.

Figure 16-54 Use a wiring diagram to identify the terminals of a relay so it can be tested properly.

PROCEDURE

If the relay is controlled on the ground side, follow this procedure to test the relay.

1. Use a testlight to check for voltage at the power feed to the relay. If voltage is not present, correct the fault in the battery feed to the relay. If there is voltage, continue testing.
2. Probe for voltage at the coil terminal. If voltage is not present, correct the fault in the battery feed to the relay. If voltage is present, continue testing.

3. Use a fused jumper wire to connect the control terminal to a good ground. If the relay works, the fault is in the control circuit. If the relay does not work, continue testing.
4. Connect the jumper wire from the battery to the output terminal of the relay. If the device operated by the relay works, the relay is bad. If the device does not work, the circuit between the relay and the device or the device's ground is faulty.

PROCEDURE

If the relay is controlled by a computer, do not use a test-light. Rather use a high-impedance voltmeter set to the 20 V DC scale, then:

1. Connect the negative lead of the voltmeter to a good ground.
2. Connect the positive lead to the output wire. If no voltage is present, continue testing. If there is voltage, disconnect the relay's ground circuit. The voltmeter should now read 0 volts. If it does, the relay is good. If voltage is still present, the relay is faulty.
3. Connect the positive voltmeter lead to the power input terminal. If near battery voltage is not measured there, the relay is faulty. If it is, continue testing.
4. Connect the positive lead to the control terminal. If near battery voltage is not measured there, check the circuit from the battery to the relay. If it is, continue testing.
5. Connect the positive lead to the relay ground terminal. If more than 1 volt is present, the circuit has a poor ground.

If the relay terminals are not accessible, remove the relay from its mounting. Use an ohmmeter to test for continuity between the relay coil terminals. If the meter indicates an infinite reading, replace the relay. If there is continuity, use a pair of jumper wires to energize the coil. Check for continuity through the relay contacts. If there is an infinite reading, the relay is faulty. If there is continuity, the relay is good and the circuits need to be tested.

Check the service manual for resistance specifications for the relay's coil and compare your readings to them. Low resistance indicates that the coil is shorted. If the coil is shorted, the transistors and/or driver circuits in the computer could be damaged due to excessive current flow.

Stepped Resistors

The best way to test a stepped resistor is with an ohmmeter. Remove the resistor and connect the

ohmmeter leads to the two ends of the resistor. Compare the readings against specifications. Make sure the ohmmeter is set to the correct scale for the anticipated amount of resistance.

A stepped resistor can also be checked with a voltmeter. Measure the voltage after each part of the resistor block and compare the readings to specifications.

Variable Resistors

A common way to test a variable resistor is with an ohmmeter; however, it can also be checked by observing the output voltage. To test a rheostat, identify the input and output terminals and connect an ohmmeter across them. Rotate the control while observing the meter. If the resistance values do not match specifications, or if there is a sudden change in resistance as the control is moved, the unit is faulty. When using a voltmeter, the readings should be smooth and consistent as the control is moved.

To test a potentiometer, connect an ohmmeter across the resistor. The readings should be within the range listed in the specifications. Then move the leads to the input and output of the resistor. Manually change the resistance. The readings should sweep evenly and consistently within the specified resistance values. The condition of a potentiometer can also be checked with a voltmeter or a lab scope. Compare the voltage changes to the specifications.

Wiring

Wire insulation should be in good condition. Broken, frayed, or damaged insulation that exposes live wires can cause shorts (**Figure 16-55**). These conditions

Figure 16-55 Broken, frayed, or damaged insulation that exposes live wires can cause shorts.

Figure 16-56 A typical printed circuit board.

can also create a safety hazard. Replace all wires that have damaged insulation.

When checking a circuit, make sure to check the ground connections, including the ground strap from the engine or other component to the chassis. An engine ground is typically a braided, flat cable. A bad ground cable can cause problems in many different circuits.

The best way to check a wire is to check the voltage drop across it. If the wire is in good shape, there should be very little or no voltage drop.

Wires are commonly grouped into a harness. A single-plug harness connector may form the connecting point for many circuits. Harnesses and harness connectors help organize the vehicle's electrical system and provide a convenient starting point for testing many circuits. Most major wiring harness connectors are located in the vehicle's dash or fire wall area.

Printed Circuits

Late-model vehicles use flexible printed circuits boards (**Figure 16-56**). Printed circuit boards are not serviceable and, in some cases, not visible. When these boards fail, the entire unit is replaced.

The following precautions should be observed when working with a printed circuit:

- Never touch the surface of the board. Dirt, salts, and acids on your fingers can etch the surface and set up a resistive condition.
- The copper conductors can be cleaned with a commercial cleaner or by lightly rubbing a pencil eraser across the surface.

- A printed circuit board is easily damaged because it is very thin. Be careful not to tear the surface, especially when plugging in connectors or bulbs.

TROUBLESHOOTING CIRCUITS

When troubleshooting an electrical problem, in any system, it is very important that a logical approach is taken. Making assumptions or jumping to conclusions can be very expensive and a total waste of time. The basic steps for diagnosis given in Chapter 2 should be followed. Here they are again, only modified to fit electrical problems:

PROCEDURE

To troubleshoot an electrical problem, follow these steps:

1. *Gather information about the problem.* From the customer find out when and where the problem happens and what exactly happens.
2. *Verify that the problem exists.* Take the vehicle for a road test or try the components of the customer's concerns and try to duplicate the problem, if possible.
3. *Thoroughly define what the problem is and when it occurs.* Pay attention to the conditions present when the problem happens. Also pay attention to the entire vehicle; another problem may be evident to you that was not evident to the customer. The most important thing is to fully understand what the problem is.
4. *Research all available information to determine the possible causes of the problem.* Look at all service bulletins and other information related to the problem.

to see if this is a common concern. Study the wiring diagram of the system and match a system or some components to the problem.

5. *Isolate the problem.* Based on an understanding of the problem and circuit, make a list of probable causes. Narrow down this list of possible causes by checking the obvious or easy to check items. This includes a thorough visual inspection.
6. *Continue testing to pinpoint the cause of the problem.* Once you know where the problem should be, test until you find it! Begin testing to determine whether or not the most probable cause is the problem. If this is not the cause, move to the next most probable cause. Continue this until the problem is solved.
7. *Locate and repair the problem, then verify the repair.* Once you have determined the cause, make the necessary repairs. Never assume that your work solved the original problem. Operate all features of the circuit to be sure that the original problem has been corrected and that there are no other faults in the circuit.

Troubleshooting Logic

Remember there are three basic types of electrical problems. Knowing the type of problem that is causing the customer's concerns will dictate what tests should be conducted. If something does not work, the problem is most likely caused by a short or an open. If the fuse for that circuit is blown, the problem is a short. If the fuse is good, the problem is an open. If a part does not work correctly, such as a dim light bulb, the problem is high resistance.

Quick voltage checks will also help define the problem. Check for voltage at the part that is not working correctly. If source voltage is present at the part, the part is bad or the ground circuit is faulty. If less than source voltage is measured at the part, there is a fault in the power feed to the part. Also, measure the voltage drop across the part; this can indicate a problem with the part. If a faulty part is suspected, it should be checked or replaced.

When making any checks with a meter, follow all safety precautions. Try to take all measurements at a connector. Because the terminals at the connector can be damaged by inserting a meter's test leads into the connector, always use the correct adapter on the ends of the test leads. Adapters are available to match the size of the terminals. Using too large of an adapter can deform the terminals. When measurements are taken at the mating side (front) of a disconnected connector, this is called **front probing**. When measurements are taken at the back or wire side of a connected connector, this is called **back probing**. Front probing is the preferred way to take measurements. At times it may be necessary to make direct contact

with a wire by piercing through the insulation. Make sure not to damage the wire and cover the pierced area with electrical tape or clear fingernail polish. This will prevent the copper wire from corroding.

The key to identifying the exact cause of the problem is limiting all testing to the components and circuits that could be causing the problem. An understanding of the problem, coupled with an understanding of the circuit, will lead to the fault. A wiring diagram will serve as the map to the problem. Your understanding and knowledge will tell you where you want to go and the wiring diagram will tell you how to get there.

Using Wiring Diagrams

During diagnosis, one of the most important sources of information is a wiring diagram. A wiring diagram shows the relationships of one circuit to the others. Based on an understanding of the diagram, electricity, and how a particular system is designed to work, testing points can be identified. Wiring diagrams are included in the electrical section of most service manuals.

Wiring diagrams contain much information about an electrical circuit (**Figure 16-57**). They contain a comprehensive look at each circuit with all the connectors, wiring, signal connections (buses) between the devices, and electrical or electronic components of the circuit. The diagrams are drawn with lines that represent wires between the appropriate connectors. The distance between the connectors is not given. Most diagrams are drawn so the front of the car is on the left of the diagram and show the power source on the top of the wiring diagram and the ground source at the bottom.

Wiring diagrams typically show the following:

- *Wires by wire numbers or color coding.* All wires are identified by circuit number, color, and/or, in some cases, size. The wiring diagram also shows the color changes at a connector or splice. Often wire color changes at a connector, these changes are noted in the diagram.
- *Wire cross-section size.* Some manufacturers indicate the wire size along with the color code.
- *Ground connections.* Most diagrams show the point at which circuits are grounded. These are typically identified with the letter "G." Often there are common grounding points.
- *Wire connection points.* Individual connectors "C" are shown and listed by number. Note: The symbol for a connector varies with the manufacturer.
- *Reference of wire continuation.* At times, the part of a wiring diagram where a particular wire

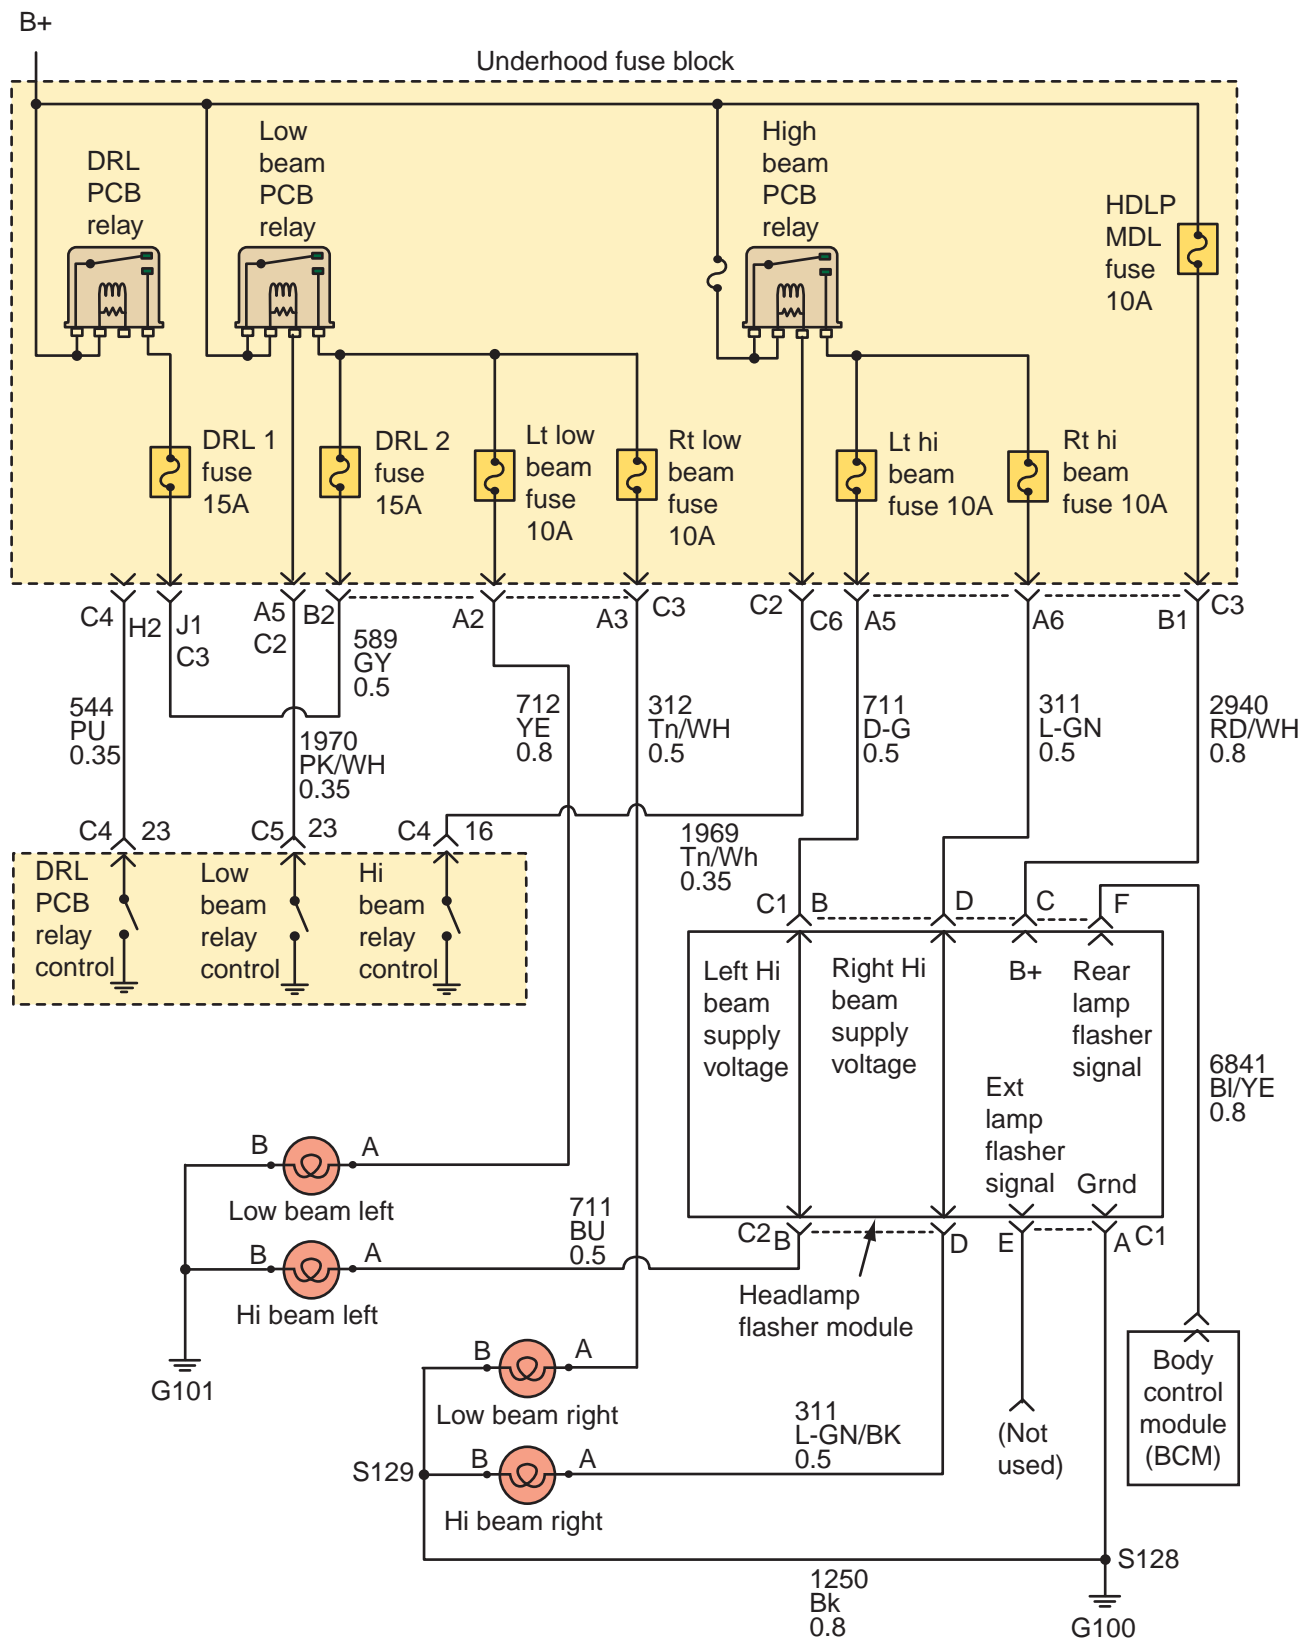

Figure 16-57 A wiring diagram of a headlight system.

continues is referenced to another diagram or a section area.

- **Location of splices.** Where a group of wires are electrically joined together is typically designated as “S.”
- **Terminal designation.** A number or other label that shows where a particular wire is located in a multipin connector.
- **Component symbols.** A wiring diagram uses a set of symbols to represent electrical components or devices. These are quite standard but may vary with the manufacturer. In most cases, the components are drawn to show the way they are connected electrically.
- **Switches.** The placement of switches in the circuit are shown in their normal (NO or NC) position.
- **Fuse designation.** Fuses and other circuit protection devices are shown by their location and rating.
- **Relay information.** The location of all relays is shown as well as the connections to its terminals.
- **Continuation of circuit.** This may be noted by an arrow that notes where a wire or circuit is continued. The reference is normally to a seemingly unrelated circuit and is noted by an arrow.

SHOP TALK

To make it easier to identify where grounds, splices, and connectors are located on the vehicle, manufacturers use a numbering system that identifies the basic location of these. For example, many manufacturers, such as GM, have a three-digit number after the G, S, and C that represents their location. Typically, 100 through 199 means that the ground, splice, or connector is under the hood, 200–299 means they are under the dash, 300–399 means they are in the passenger compartment, and 400–499 means they are in the trunk.

Getting the Right Diagram Wiring diagrams are only valuable if they are the correct ones for the vehicle and show the circuit and/or components you wish to test. The wiring diagram should be for the exact year, make, and model of the vehicle. Most electronic service information systems will match the wiring diagram to the VIN. To retrieve a wiring diagram that will help in diagnosis of a problem, match the component to the index for the wiring diagram. The index will list a letter and number for each major component and

many different connection points. Refer to those references. Most electronic information systems will automatically display the appropriate diagram once the component is selected.

For some vehicles, only total vehicle wiring diagrams are available. These can make it more difficult to locate the circuit you need. These diagrams also have an index that will identify the grid where a component can be found. The diagram is marked into equal sections by grid letters and numbers on the outside borders like a street map. If the wiring diagram is not indexed, you can locate the component by relating its general location in the vehicle to a general location on the wiring diagram.

Tracing a Circuit After you have the correct wiring diagram, identify all of the components, connectors, and wires that are directly related to that component. This is done by tracing through the circuit, starting at the component. Tracing through the circuit should identify the source of power for the component and its ground circuit. It also will identify all related controls. Tracing the circuit also allows you to understand the operation of the circuit. This is important because it will help determine where to test the circuit and what to expect at those test points. Remember, all electrical circuits have a power source, a load, and a path to ground. Make sure these are identified.

Tracing the circuit will also simplify complex wiring diagrams. Complex wiring diagrams are made up of many individual circuits. Some are directly interrelated and others are not. When the circuit of concern is pulled out of the wiring diagram, it is much easier to identify its wires and components. It also reduces the chances of being distracted by wires that probably are not the cause of the problem.

After you have traced the circuit, study it and make sure you know how the circuit is supposed to work. Then describe the problem and ask yourself what could cause this. Limit your answers to what is included in your traced wiring diagram. Also limit your answers to the description of the problem. It is wise to make a list of all probable causes of the problem then number them according to probability. For example, if all of the lights in the instrument panel do not work, it is most probable that the cause is not all bad bulbs. Rather it is more likely that the fuse or power feed is bad. After you have listed the probable causes, in order of probability, then look at the wiring diagram to identify how you can quickly test to find out if each is the cause.

Tracing the circuit can be done in one of two ways, neither of which involves marking a wiring diagram in a manual. Tracing can be done by drawing out the

circuit on a piece of paper. It does not need to be pretty; it just needs to be accurate. Draw the component (can be a simple box) and draw all wires and controls that supply the power and ground; include all controls. Mark each wire with its color and make sure to note any change in color. Also label all controls and components that are included in the circuit.

Tracing can also be done by using highlighters or markers to color a copy of the wiring diagram. There are many different ways to do this; the one given here is just a suggestion. Developing your own method will work as long as you remain consistent. Find the component of concern in the wiring diagram and outline it in yellow. Follow the power wires toward the power source. The source can also supply power to other components, but ignore them for the time being. Trace the power wire leading to the component to the point where it connects to a control or load. Color that wire red. That wire should have source voltage. If the control is an on-off switch, source voltage will be present when the switch is closed; color the wire leading from the control to the component orange. If the control will pass a variable amount of voltage to the component, color the output wire green. Now look at the ground side of the component. If the path to ground is direct with no control, color that wire black. If the ground path has a control, color the wire to the control blue and the wire from the output of the control to ground black.

Coloring the circuit as described allows for a simple reference as to what to expect at each wire in the circuit. The red wire(s) should always have source voltage. The orange wire will only have source voltage when the control is closed. The voltage on the green wire will vary with changes at the control. The black wire should have 0 volts at all times. However, the blue wire should have source voltage when the control is open and 0 volts when it is closed. Your testing should be based on this logic. Use the wiring diagram to identify the test points. **Figure 16-58** shows the circuit of the right low beam headlight. This is the same diagram as used in Figure 16-57, but only the parts of the circuit that could cause a problem with one headlamp are noted. Note that all wires and components that would affect more than that headlamp are not traced. Doing this certainly simplifies diagnosing the circuit.

If the power source for the component feeds more than one component or the ground is shared by others, check the operation of those components. If they operate normally, you know that the common power and ground circuits are good. Therefore, the problem must be between the common points. Likewise if the

other components do not work correctly, you know that the problem is within the common part of the circuit.

TESTING FOR COMMON PROBLEMS

It would take thousands of pages to describe all of the possible combinations of electrical problems. But you are in luck. *All* problems can be boiled down to one of three problems. Identifying which one you are looking for will define what tests you need to conduct.

Testing for Opens

An open is evident by an inoperative component or circuit. Study the wiring diagram for the component. Begin your testing at the most accessible place in the circuit and work from there. Check for voltage at the positive side of the load. If there are 0 volts, move to the output of the control (**Figure 16-59**). If there are at least 10.5 volts, the open is between the control and the load. If the reading is 10.5 volts or higher, check the ground side of the load. If the voltage there is 1 volt or lower and the load does not work, the load is bad. If the voltage at ground is greater than 1 volt, there is excessive resistance or an open in the ground circuit. If the voltage at the positive side of the load is less than 10.5 volts but above 0 volts, move the positive lead of the voltmeter toward the battery, testing all connections along the way. If 10.5 volts or more are present at any connector, there is an open or high resistance between that point and the point previously checked. If battery voltage is present at the ground of the load, there is an open in the ground circuit. Use a jumper wire to verify the location of the open.

Testing for Shorts

Use an ohmmeter to check for an internal short in a component. If the component is good, the meter will read the specified resistance or at least some resistance. If it is shorted, it will read lower than normal or zero resistance. Also, if the component has more than two terminals or pins, check for continuity across all combinations of these. Refer to the wiring diagram to see where there should be continuity. Any abnormal readings indicate an internal short.

When a fuse is blown, this probably is due to a wire-to-wire short or a short to ground. To test these circuits, a special jumper wire with a circuit breaker should be used as a substitute for the blown fuse. The jumper wire is fit with a 10- or 20-amp self-resetting circuit breaker. This will allow for testing the circuit

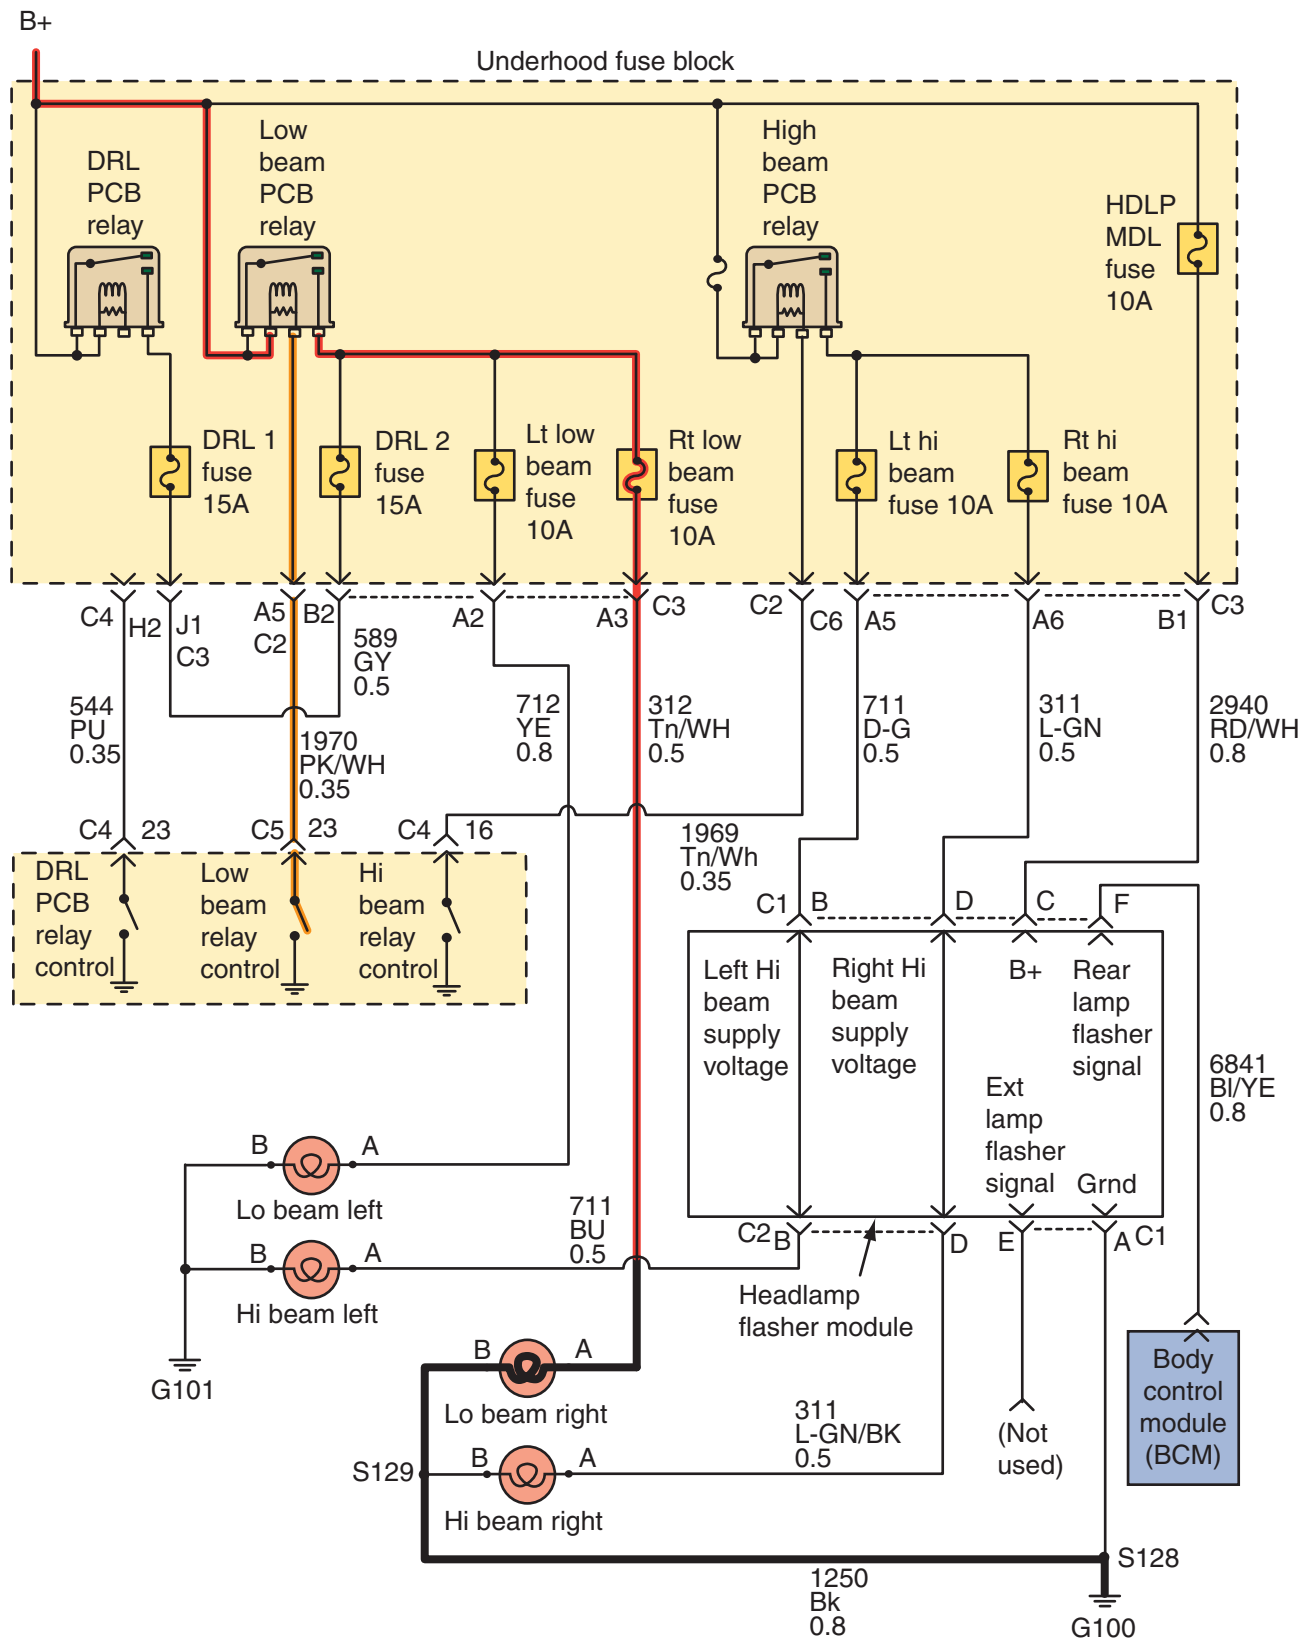

Figure 16-58 Figure 16-57 with the right low beam circuit traced.

without causing damage to the wires and components in the circuit. Some tool companies include a buzzer inline with the breaker.

When a wire-to-wire short is suspected, check the wiring diagram for all of the affected components.

Identify all points where the affected circuits share a connector. Check the circuit protection devices for the circuits. High current due to the short will cause this. Check the wiring for signs of burned insulation and melted conductors. If a visual inspection does

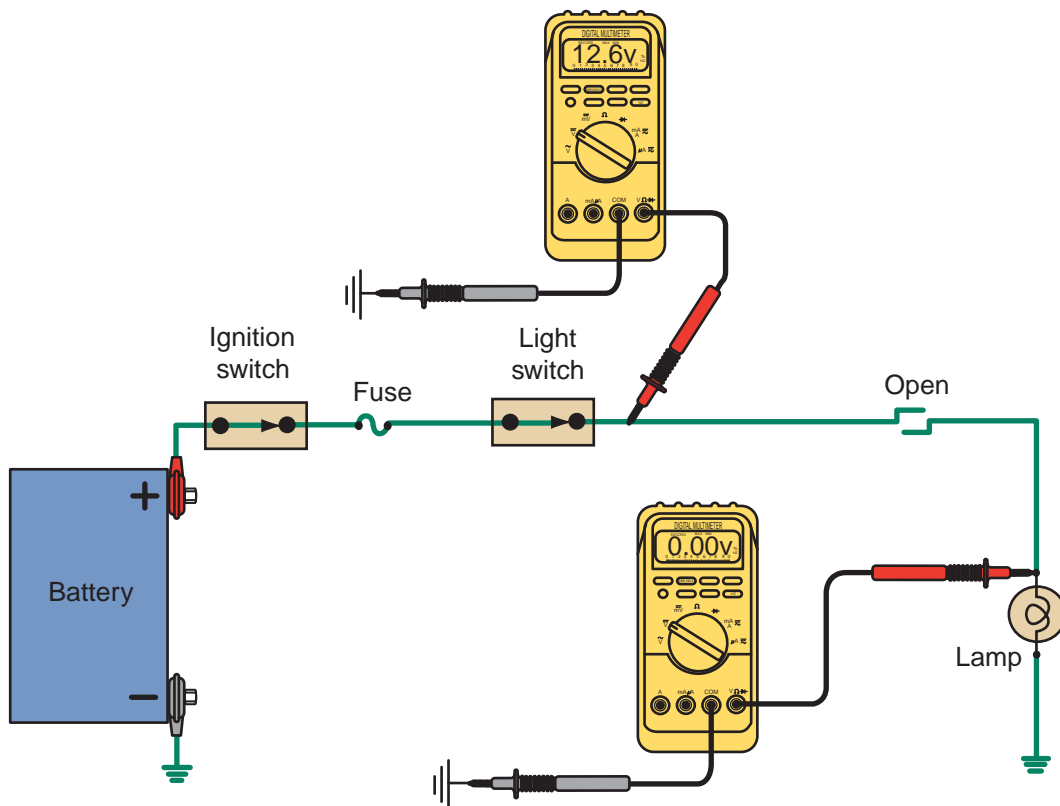

Figure 16-59 If you have 0 volts at the load, test the output of the switch. If there is power there, the open is between the switch and the load.

not identify the cause of the short, remove one of the fuses for the affected circuits. Install the special jumper wire across the fuse holder terminals. Activate that circuit and disconnect the loads that should be activated by the switch. This will create open circuits and, normally, current will not flow. If sound is coming from the buzzer in the jumper wire, current is still flowing somewhere in the circuit. Disconnect all connectors in the circuit one at a time. If the buzzer stops when a connector is disconnected, the short is in that circuit.

If the problem is a short to ground, the circuit's fuse or other protection device will be open. If the circuit is not protected, the wire, connector, or component will be burned or melted. To keep current flowing in the circuit so you can test it, connect the special jumper wire across the fuse holder. The circuit breaker will cycle open and closed, allowing you to test for voltage in the circuit. Connect a testlight in series with the cycling circuit breaker. Using the wiring diagram, identify the location of the connectors in the circuit. Starting at the ground end of the circuit, disconnect one connector at a time. Check the testlight after each connector. The short is in the circuit that was disconnected when the light went out.

An alternative to this method uses a DMM (**Figure 16-60**). Remove the bad fuse and disconnect the load. Connect the DMM across the fuse termi-

Figure 16-60 Through the process of elimination, the source of a short can be found.

nals. Refer to the wiring diagram to see if the ignition switch needs to be turned on to energize the circuit. If the meter reads a voltage, there must be a short before the load. Starting with the circuit's

Figure 16-61 Many manufacturers do not recommend using a circuit breaker as a substitute for the fuse during testing; rather a sealed beam headlight is connected with jumper wires across the fuse holder.

wiring closest to the fuse, wiggle the wiring harness. Do this in short steps all along the wire. The point at which the voltage drops to zero is close to where the short is.

SHOP TALK

Many manufacturers do not recommend using a circuit breaker as a substitute for the fuse during testing; rather a sealed beam headlight (Figure 16-61) is connected with jumper wires across the fuse holder. The headlight serves a load and limits the current in the circuit. The headlight will light as long as current is flowing through the circuit.

Short Detector Some technicians use a compass or Gauss gauge to find the location of a short

(Figure 16-62). A magnetic field is formed around a current-carrying conductor and a compass reacts to magnetic fields. The shorted circuit will have high current; therefore, a large magnetic field will be formed around the shorted circuit. With the wiring diagram and other service information, locate the routing of the wires in the affected circuit. Connect the jumper wire with a circuit breaker across the fuse holder for the blown fuse. Position the compass over or close to the wiring harness. The magnetic field in the wire will cause the compass' needle to move away from its north position. As the circuit breaker cycles, the needle will fluctuate. As the compass is slowly moved across the wire, it will continue to fluctuate until it passes the point where the short is. To find the exact location of the short, inspect the wire in that area. Look for signs of overheating and broken, cracked, exposed, or punctured wires.

Figure 16-62 Use a compass to locate the cause of a short.

Figure 16-63 A simple light circuit with unwanted resistance. Notice the reduced voltage drop across the lamp and the reduced circuit current.

Testing for Unwanted Resistance

High-resistance problems are typically caused by corrosion on terminal ends, loose or poor connections, or frayed and damaged wires. Carefully inspect the affected circuit.

Whenever excessive resistance is suspected, both sides of the circuit should be checked. Begin by checking the voltage drop across the load (**Figure 16-63**). This should be close to battery voltage unless the circuit contains a resistor located before the load. If the voltage is less than desired, check the voltage drop across the circuit from the switch to the load. If the voltage drop is excessive, that part of the circuit contains the unwanted resistance. If the voltage drop was normal, the high resistance is in the switch or in the circuit feeding the switch.

Check the voltage drop across the switch. If the voltage drop is excessive, the problem is the switch. If the voltage drop is normal, the high resistance is in the circuit feeding the switch. If battery voltage is present at the load, the ground circuit for the load should be checked. Connect the red voltmeter lead to the ground side of the load and the black lead to the grounding point for the circuit. If the voltage drop is normal, the problem is the grounding point. If the voltage drop is excessive, move the black meter lead toward the red. Check voltage drop at each step. Eventually you will read a high-voltage drop at one connector and then a low-voltage drop at the next. The point of high resistance is between those two test points. If the voltage drop is normal, the high resistance is in the switch or in the circuit feeding the switch.

CONNECTOR AND WIRE REPAIRS

Many electrical problems can be traced to faulty wiring or connections. Loose or corroded terminals; frayed, broken, or oil-soaked wires; and faulty

insulation are the most common causes. Wires, fuses, and connections should be checked carefully. Keep in mind that a wire's insulation does not always appear to be damaged when the wire inside is broken. Also, a terminal may be tight but still may be corroded.

Check all connectors for corrosion, dirt, and looseness. Nearly all connectors have pushdown release-type locks (**Figure 16-64**). Make sure these are not damaged. Many connectors have covers over them to protect them from dirt and moisture. Make sure these are properly installed to provide for that protection.

Never reroute wires when making repairs. Rerouting wires can result in induced voltages in nearby components. **Induced voltages** produce unwanted signals through magnetism rather than from the components within the circuit. These stray voltages can interfere with the function of electronic circuits.

WARNING!

When working with connectors, never pull on the wires to separate the connectors. This can create an intermittent contact and an intermittent problem that can be very difficult to find later. Always use the special tools designed for separating connectors to prevent this problem.

SHOP TALK

Apply dielectric grease to all connections before you assemble them. This will prevent future corrosion problems. Some manufacturers suggest using petroleum jelly at the connectors.

Replacement Wire Selection

Often electrical problems require the replacement of a wire or two. It is important that this is done in a way that corrects the original problem but does not create a new problem. All replacement wires should be of the same size or larger than the original. If adding an accessory, the new wire should be large enough to ensure safe and reliable performance. However, overly large wires add weight and expense, and add to the difficulty of splicing wires together. If the wire is too small, an unwanted voltage drop can occur. The two factors that should always be considered when determining the correct size of a wire are the total circuit

Figure 16-64 Different multiple-wire shell connectors and their locking mechanisms.

TABLE 16-2 AMPERAGE CAPACITY ACCORDING TO WIRE SIZE AND LENGTH

Approx. circuit current in amps at 12 V:	Required wire gauge per length in feet								
	3	5	7	10	15	20	25	30	40

amperage and the total length of wire (resistance increases with length) used in each circuit, including the ground. Allowance for the circuits, including grounds, has been computed in **Table 16-2**.

WARNING!

Supplemental restraint system (SRS) air bag harness insulation and the related connectors are usually color coded yellow or orange. Do not connect any accessories or test equipment to SRS-related wiring.

Connecting Wires

When a section of a wire needs to be replaced, it needs to be connected to an existing wire. Cut the damaged end of the wire from the main wire. Match the dimensions of the new wire to the old one. Measure the required length of the replacement wire; make sure it is slightly longer than the section that was removed. Then connect the two wires together. After the connection is made, the joint should be wrapped with tape or covered with heat-shrink tubing.

There are several ways that the original wire can be connected to the replacement wire. Some technicians use butt connectors; these can provide a good joint between the wires. However, the preferred way

to connect wires or to install a connector is by soldering. Soldering joins two pieces of metal together by melting a lead and tin alloy and allowing it to flow into the joint. A soldering iron or gun is used to heat the solder. There are different types of solder, but only rosin-type or resin-type flux core solder should be used for electrical work.

Soldering is also used to mount components in circuit boards. Although this is not a typical procedure for an automotive technician, it should be noted that doing this requires great heat control. The heat from the soldering iron or gun can destroy electronic components. Also, when making wire repairs on or near an electronic component, use a heat sink to prevent the heat from traveling into the part.

Before using a soldering iron, make sure the tip is clean and tinned. The tip is made of copper, which corrodes through use. A corroded tip cannot transfer heat as it should. Use a file to remove all residue from the tip. When finished, the tip should be smooth and flat. Turn the iron on and allow it to heat. Then dip the hot tip into some soldering rosin flux. Remove the tip from the flux and immediately apply rosin core wire solder to all surfaces. The solder should flow over the tip. The tip is now tinned.

Photo Sequence 13 shows the procedure for soldering two copper wires together. Some manufacturers use aluminum in their wiring. Aluminum cannot be soldered. Follow the manufacturer's guidelines

Soldering Two Copper Wires Together

P13-1 Tools required to solder copper wire: 100-watt soldering iron, 60/40 rosin core solder, crimping tool, splice clip, heat shrink tube, heating gun, and safety glasses.

P13-2 Disconnect the fuse that powers the circuit being repaired. Note: If the circuit is not protected by a fuse, disconnect the ground lead of the battery.

P13-3 Cut out the damaged wire.

P13-4 Using the correct size stripper, remove about ½ inch of the insulation from both wires.

P13-5 Now remove about ½ inch of the insulation from both ends of the replacement wire. The length of the replacement wire should be slightly longer than the length of the wire removed.

P13-6 Select the proper size splice clip to hold the splice.

Soldering Two Copper Wires Together (*continued*)

P13-7 Place the correct size and length of heat shrink tube over the two ends of the wire.

P13-8 Overlap the two splice ends and center the splice clip around the wires, making sure that the wires extend beyond the splice clip in both directions.

P13-9 Crimp the splice clip firmly in place.

P13-10 Apply the tip flat of the soldering iron against the splice to heat it. At the same time, apply solder to the opening of the clip. Do not apply solder to the iron. The iron should be 180 degrees away from the opening of the clip. As the splice and wires heat, the solder will flow through the splice.

P13-11 Place the hot soldering iron in its stand and unplug it. After the solder cools, slide the heat shrink tube over the splice.

P13-12 Heat the tube with the hot air gun until it shrinks around the splice. Do not overheat the heat shrink tube.

and use the proper repair kits when repairing aluminum wiring.

WARNING!

Never use acid core solder. It creates corrosion and can damage electronic components.

Before splicing wires together, make sure the ends of the wires are clean. The correct size splice clip must be used. The size is based on the outside diameter of the wire, not the insulation. When inserting the wires into the joint, make sure that only the conductor enters the splice. Also make sure that the ends of the wires overlap each other inside the splice. Slip the jaws of the crimping tool over the center of the splice. Squeeze the crimping tool until the contact points of the crimper's jaws make contact with the splice. Then check the placement of the wires inside the splice and apply pressure to the crimping tool to form a tight crimp.

SHOP TALK

Rather than use a splice, some technicians twist the wire ends tightly together before soldering the joint. When doing this, it is important to realize that the solder does not provide for a mechanical joint. Therefore, it is important that the twisting provides a secure joint before soldering.

After a joint has been made, it must be insulated. This can be done with heat shrink tubing or tape. When using tape, place one end on the wire about 1 inch from the joint. Tightly wrap the tape around the wire. As the tape is being wrapped, about one-half of the previous wrap should be covered by the tape as it completes one turn around the wire. Once the wrapping has reached 1 inch beyond the joint, cut the tape. Firmly press on the tape at that end to form a good seal.

When using heat shrink tubing, make sure the tubing is slightly larger than the diameter of the splice. Cut a length of the tubing so that it is longer than the splice. Before joining the wires together, slip the tubing over one of the wires. Proceed to make the joint. After the wires are connected, move the shrink tubing over the splice. Use a heat gun and heat the tubing until it shrinks tightly around the

splice. The tubing will only shrink a certain amount; therefore, do not continue to heat it after it is in place. Doing this can melt the tubing and/or the insulation of the wire.

Wire Terminals and Connectors

Many different types of connectors, terminals, and junction blocks are used on today's vehicles. In most cases, the type used in a particular application is shown in a wiring diagram. Wire end terminals are used as connecting points for wires. They are generally made of tin-plated copper and come in many shapes and sizes. They may be either soldered or crimped in place. When installing a terminal, select the appropriate size and type of terminal. Be sure it fits the unit's connecting post or prongs and it has enough current-carrying capacity for the circuit.

WARNING!

Always follow the manufacturer's wiring and terminal repair procedures. On some components and circuits, manufacturers recommend complete wiring harness replacement rather than making repairs to the wiring. For most vehicles, SRS air bag harness components, including wiring, insulation, and connectors, should not be repaired (Figure 16-65). Any SRS harness damage requires replacement of the related harness.

Figure 16-65 The wiring for SRS systems has yellow connectors, and all precautions and service procedures for dealing with these should be followed.

When a connector needs to be replaced because the original has melted or is otherwise damaged, attempt to replace it with the same type and size. Often this is difficult because so many different types are used and parts departments do not have all the various designs available. Normally the available connectors are based on common shapes with a common number of terminal cavities. Therefore, it is best to use a connector that meets the need; this may mean that some of the terminal cavities are left empty. For example, if the original connector has six terminals but the available replacement has eight, arrange the wire connections to the connector as if the connector had six. This will keep the wires in order for future diagnostics and leave the end pair blank. Of course, to do this, the male and female ends of the connector must be replaced. Sometimes, the replacement connector will require different terminal ends than the original. This requires the replacement of terminal ends on the wires for the male and female connectors.

Replacing a Terminal

Terminal ends are replaced when they are damaged or to accommodate the use of a connector. The replacement process must be done to provide for good continuity and to prevent electrical problems in the future.

PROCEDURE

To replace a terminal end on a wire, follow this procedure:

1. Use the service information to identify the type of terminal that should be used, the position of the locking clips, and the terminal unlocking procedures for that connector.
2. Use a small screwdriver or terminal pick (**Figure 16-66**) to unlock the secondary locking device.
3. Gently push the terminal into the connector and hold it there.
4. Insert the terminal pick into the connector and move the locking clip to the unlock position and hold it there.
5. Carefully pull the terminal from the connector by pulling the wire toward the rear of the connector. Do not use too much force.
6. Measure the diameter of the wire's insulation with a micrometer or vernier caliper.
7. Identify the type of terminal and use the measurement to select the correct size for the replacement terminal.
8. Select the correct size for the replacement wire.
9. Cut the old terminal from the wire in the harness.

10. Use the old wire as a guide and cut the replacement wire slightly longer. Be careful when doing this because if the wire is too short, there will be tension on the terminal, splice, or connector, which can lead to an open circuit. If the wire is too long, it may get pinched and cause a short.
11. Strip the insulation from the wire (**Figure 16-67**) in the harness and both ends of the replacement wire. Normally, $\frac{3}{8}$ inch of insulation should be removed.
12. Make sure the strands of wire are not damaged while removing the insulation.
13. Place the ends of the wires into the terminal and connectors and crimp the terminal (**Figure 16-68**). To get a proper crimp, place the open area of the connector facing toward the anvil of the tool. Make sure the wire is compressed under the crimp.

WARNING! Do not crimp a terminal with the cutting edge of a pair of pliers. Although this method may crimp the terminal, it also weakens it.

14. If heat shrink will be used to seal the connections, slip the appropriate length of tubing over the end of the wire that will be spliced.
15. Install the terminal into the connector. Make sure the locking clip is in the proper position. If it is not, use the terminal pick to gently bend it back to its original shape.
16. Push the terminal into the connector until a click is heard.
17. Gently pull on the wire. If the terminal is locked in the connector, it will not move.
18. Connect both sides of the connector and secure the secondary locking device.
19. Tape the new wire to the wiring harness (**Figure 16-69**). If the harness is contained in conduit, make sure it is fully enclosed and tape the outside of the conduit.

Figure 16-66 Terminal picks are used to unlock terminal and connector locks.

Figure 16-69 Tape all wire repairs to prevent corrosion and damage.

CASE STUDY

A customer tells the technician that the fuse for the windshield wiper blows as soon as he replaces it and turns on the wipers.

The technician removes the fuse and observes that it is black inside. The technician knows that these symptoms indicate a short to ground and so substitutes a 12-volt testlight for the blown fuse. With the testlight in place, the technician disconnects the wiper motor (a mechanically grounded load component), turns the ignition switch on, and notes the status of the testlight. Because the motor is disconnected, the circuit should be open and the testlight is lit. The technician knows that the problem is not in the motor. The problem is a short to ground in the wiring that leads to the motor. The technician continues the search for the short by separating circuit connectors one at a time. He starts at the connector that is farthest from the testlight and works toward the fuse panel. The light remains on when the technician unplugs the first connector so he knows that the short exists in some part of the circuit that is still intact. The light goes off when the technician unplugs the next connector one step closer to the fuse panel. The technician then realizes that the short is somewhere between the last two connectors unplugged because the testlight indicates that there is no longer a path to ground. The technician visually inspects the wiring between the two connectors and discovers and repairs a bare spot in the wire that was contacting ground.

KEY TERMS

Average responding	Inline fuse
Back probing	Open
Digital storage oscilloscope (DSO)	Radio frequency interference (RFI)
Front probing	Root mean square (RMS)
Glitches	Schematics
Graphing multimeter (GMM)	Short
Induced voltage	

SUMMARY

- All electrical problems can be classified as an open, short, or high-resistance problem. Identifying the type of problem will allow for the identification of the correct tests to conduct when diagnosing an electrical circuit.
- Wiring diagrams show where wires are connected, the circuit's components, the color of the wires' insulation, and sometimes the wire gauge size.
- Voltmeters, ohmmeters, ammeters, and volt/amp meters are used to test and diagnose electrical systems. These are used with jumper wires, testlights, and variable resistors.
- Multimeters are multifunctional and can test DC and AC volts, ohms, and amperes. Some multimeters can also be used to measure engine rpm, duty cycle, pulse width, frequency, and temperature.
- There are two ways that DMMs display AC voltage: RMS and average responding.
- Some DMMs also feature a MIN/MAX function, which displays the maximum, minimum, and average voltage the meter recorded during the time of the test.
- On a lab scope, an upward movement of the trace indicates an increase in voltage, and a downward movement of this trace represents a decrease in voltage. As the trace moves across the screen, it represents a specific length of time.
- To troubleshoot a problem, begin by verifying the customer's complaint. Then operate the system and others to get a complete understanding of the problem. Use the correct wiring diagram and identify testing points and probable problem areas. Test and use logic to identify the cause of the problem.
- Wiring diagrams are invaluable for diagnostics. Tracing the diagram allows you to think about how the circuit should work and where it should be tested.

- Many automotive electrical problems can be traced to faulty wiring, such as loose or corroded terminals; frayed, broken, or oil-soaked wires; and faulty insulation.
- The preferred way to connect wires or to install a connector is by soldering. Never use acid core solder. It creates corrosion and can damage electronic components.

REVIEW QUESTIONS

1. How will an electrical circuit behave if there is an open in the circuit?
2. What happens to an electrical circuit when there is unwanted resistance in it?
3. An ammeter is always connected _____ with the circuit, whereas a voltmeter is connected in _____ with the circuit.
4. Which of the following is *not* a typical cause of unwanted or high resistance in a circuit?
 - a. corrosion on terminal ends
 - b. a power wire contacting the chassis
 - c. loose or poor connections
 - d. frayed and damaged wires
5. Refer to **Figure 16-70**. According to the color scheme used to trace a circuit that is given in the text, what color should wire A-B be?
 - a. red
 - b. blue
 - c. green
 - d. yellow
6. Refer to **Figure 16-71**. According to the color scheme used to trace a circuit that is given in the text, what wire is colored wrong?
 - a. A-B
 - b. B-C
 - c. B-F
 - d. D-E

Figure 16-70

**Figure 16-71**

7. *True or False?* A zero reading on an ohmmeter means the circuit or component is open.
8. *True or False?* The maximum allowable voltage loss due to voltage drops across wires, connectors, and other conductors in a 12-volt circuit is 1.2 volts.
9. What type of solder should be used to repair electrical wiring?
10. Which of the following lab scope controls must be set when trying to observe the timing of something?
 - a. intensity
 - b. vertical
 - c. horizontal
 - d. trigger
11. Which of the following statements is true?
 - a. A short to ground causes decreased current flow.
 - b. An open causes unwanted voltage drops.
 - c. High-resistance problems cause increased current flow.
 - d. Both open and high-resistance problems may cause a load not to work.
12. *True or False?* When tracing a circuit in a wiring diagram, remember that all circuits have a power source, a load, and a path to ground and they need to be identified.
13. What would the results of a voltage drop test be if the circuit is open?
14. Which of the following information is not given in a wiring diagram?
 - a. wire-by-wire color coding
 - b. location of wire harness travel
 - c. terminal designation
 - d. component designations
15. *True or False?* While troubleshooting a problem, the key to identifying the exact cause of the problem is testing all of the vehicle's components and circuits until the problem is found.

ASE-STYLE REVIEW QUESTIONS

1. While discussing electricity: Technician A says that an open causes unwanted voltage drops. Technician B says that high-resistance problems cause increased current flow. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
2. While discussing NTC thermistors: Technician A says that some systems use this type of thermistor as a protection device. Technician B says that when there is high current in a circuit, the resistance of the thermistor increases and causes a decrease in current flow. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
3. While measuring the resistance of a wire with an ohmmeter: Technician A says that if low resistance is shown on the meter, the wire is basically good. Technician B says that if no resistance is measured, the wire is shorted. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
4. While testing variable resistors: Technician A says that while checking a rheostat with a voltmeter, the voltage should change smoothly with a change in the control. Technician B says that a potentiometer should be checked with a testlight. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
5. While using an ohmmeter to measure the resistance values of a component: Technician A says that if the component has less than the specified resistance, the part is open. Technician B says that if there is more resistance than called for, the part is shorted. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
6. Technician A uses an ohmmeter to test circuit protection devices. Technician B uses a voltmeter to test circuit protection devices. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
7. Technician A uses a testlight to detect resistance. Technician B uses a jumper wire to test circuit breakers, relays, and lights. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B

8. While diagnosing the location of a wire-to-wire short: Technician A checks the wiring of the affected circuits for signs of burned insulation and melted conductors. Technician B checks common connectors shared by the two affected circuits. Who is correct?
- a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
9. While measuring resistance: Technician A uses an ohmmeter to measure resistance of a component before disconnecting it from the circuit. Technician B uses a voltmeter to measure voltage drop. A circuit with very low resistance will drop zero or very little voltage. Who is correct?
- a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
10. While discussing how to test a switch: Technician A says that the action of the switch can be monitored by a voltmeter. Technician B says that continuity across the switch can be checked by measuring the resistance across the switch's terminals when the switch is in its different positions. Who is correct?
- a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B

BATTERIES: THEORY, DIAGNOSIS, AND SERVICE

OBJECTIVES

- Describe how a battery works.
- List the precautions that must be adhered to when working with or around batteries.
- Describe the basic construction of an electrochemical cell.
- Explain how electrochemical cells can be connected to increase voltage and current.
- Explain the different methods used to recharge a battery.
- List and describe the various ways a battery may be rated.
- List and describe the various types of batteries according to their chemistries that may be used in automobiles.
- List the precautions that must be adhered to when working with or around high-voltage systems.
- Describe the construction and operation of a lead-acid battery.
- Describe the various types of lead-acid batteries that are available today.
- Describe the basic services and testing procedures for a lead-acid battery.
- Describe the construction and operation of a nickel-metal hydride battery.
- Describe the construction and operation of a lithium-based battery.

INTRODUCTION

The primary source for electrical power in all automobiles is the battery. The battery has undergone many changes through the years. The introduction of hybrid vehicles and the promise of fuel cell vehicles have drastically changed the basic design of an automotive battery. Many different types of batteries are available or under development to exceed the needs of hybrid or fuel cell vehicles. Lead-acid batteries have been, and continue to be, the power source for conventional vehicles. Each of these energy-storing devices is discussed in this chapter.

BASIC BATTERY THEORY

Electrical current is caused by the movement of electrons from something negative to something positive. The strength of the attraction of the electrons (negative) to the protons (positive) determines the amount of voltage present. When a path is not present for the electrons to travel through, voltage is still present but there is no current flow. When there is a path, the electrons move and there is current. This is the basic operation of batteries.

Basic Construction

Batteries are devices that convert chemical energy into electrical energy. Chemical reactions that produce electrons are called **electrochemical reactions**. A battery stores DC voltage and releases it when it is connected to a circuit. Inside the battery are two **electrodes** or **plates** surrounded by an electrolyte. These three elements make up an electrochemical cell (**Figure 17-1**). Batteries are normally made up of electrochemical cells connected together.

Figure 17-1 A simple electrochemical cell.

One of the plates has an abundance of electrons (negative plate) and the other has a lack of electrons (positive plate). The electrons want to move to the positive plate and do so when a circuit connects the two plates. Batteries have two terminals, a positive that is connected to the positive plate and a negative that is connected to the negative plate.

Electrolytes are chemical solutions that react with the metals used to construct the plates. These chemical reactions cause a lack of electrons on the positive electrode and an excess on the negative electrode. When connected into a circuit, the electrons move. The reactions continue to provide electrons for current flow until the circuit is opened or the chemicals inside the battery become weak. At that time, the battery has run out of electrons (the battery is worn out), the number of electrons on the positive and negative sides are equal, or all of the protons are matched with an electron. Recharging simply moves the electrons that moved to the positive electrode back to the negative electrode (**Figure 17-2**).

Charging

Charging a battery restores the chemical nature of the cells. To do this, a chemical reaction takes place, causing current flow within the cells. Discharging allows for current flow outside the cell. To understand the charging process, remember that current flows from a higher potential (voltage) to a lower potential. If the voltage applied by an outside source to the battery is higher than the voltage of the battery, current will flow into the battery. This means the charging voltage must be higher than the battery's voltage in order to charge it.

Each battery design has its own charging requirements. It is very important to follow the correct procedure for the battery being charged. It is also important to prevent the battery from overheating

during charging and to use the correct type of charger; these too vary with battery designs. Using the wrong charger can destroy the batteries or charger.

Cell Arrangements

The voltage produced by an individual battery cell varies with the chemicals and materials used to construct the cell. Most cells produce between 1.2 and 4 volts. To provide higher voltages, cells are connected together. In addition, there is a limited amount of current available from an individual cell, so to increase available current, cells are connected together. Cells can be connected in series or in parallel, or both.

Series Connections Cells are connected in series to provide higher voltages. In this arrangement, the total voltage is the sum of the voltages in each cell. For example, a lead-acid cell, commonly used in starting batteries, produces about 2.1 volts. By connecting six together in series, the battery has a voltage of 12.6 volts. Series connections have the positive terminal of one cell connected to the negative terminal of another, the positive terminal of that cell connected to the negative of another, and so on (**Figure 17-3**). Individual batteries can also be connected in series. Forty-two-volt systems use a 36-volt battery pack, which can be made from three 12-volt batteries (**Figure 17-4**) or eighteen 2-volt cells connected in series. Forty-two volts are provided by the charging system.

Parallel Connections Cells are connected in parallel to increase the amperage of the pack of cells. The positive terminals are connected together, and all the negative terminals are connected together. The total amperage is the sum of amperages from each cell. The voltage is equal to the voltage of an individual cell.

Series-Parallel Connections In this arrangement, groups of cells are wired in parallel and then those groups are connected in series. This arrangement

Figure 17-2 The flow of electrons in a battery while discharging and charging.

Figure 17-3 When individual cells are connected in series, the total voltage is equal to the sum of the cells.

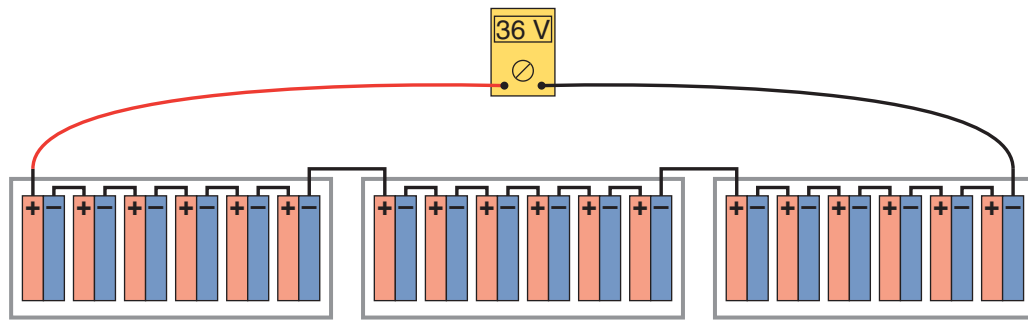

Figure 17-4 A 36-volt battery pack can be made from three 12-volt batteries or eighteen 2-volt cells connected in series.

provides for increases in voltage and amperage. Any number of cells can be connected in parallel as long as each group of parallel cells that are wired in series has the same power output.

Battery Hardware

In order to connect the battery to the vehicle's electrical system, battery cables are used. They must safely handle the voltage and current demands of the vehicle. Battery holddowns are used to prevent damage to the battery, and heat shields are sometimes used to keep battery temperatures down. Most high-voltage battery packs are enclosed in a box that serves to secure the pack and to keep it within a particular temperature range.

Battery Cables Battery cables must be able to carry the current required to meet all demands. Normal 12-volt cable size is 4 or 6 gauge. Various forms of clamps and terminals are used to ensure a good electrical connection at each end of the cable (**Figure 17-5**). Connections must be clean and tight to prevent arcing and corrosion. The positive cable is normally red and the negative cable is black.

Figure 17-5 The battery cable is designed to carry the high current required to start the engine and supply the vehicle's electrical systems.

The high-voltage cables in nearly all hybrid vehicles are colored orange and have markings on them. Sometimes the cables are enclosed in an orange casing. It is important to remember that some hybrids power other accessories with high voltage; these cables are orange just like the battery cables (**Figure 17-6**).

Battery Holddowns All batteries must be held securely in the vehicle to prevent damage to the battery and to prevent the terminals from shorting to the vehicle. Battery holddowns are made of metal or plastic (**Figure 17-7**).

Cooling System The performance and durability of batteries, especially high-voltage battery packs, are

Figure 17-6 High-voltage cables are colored orange or are encased in an orange covering.

Figure 17-8 This assembly holds the battery pack and provides airflow to keep the batteries cool.

heavily dependent on maintaining desired temperatures. Batteries may be housed in a box or container with a cooling fan. The box not only secures the batteries, but also serves as a conduit for the air from the fan (**Figure 17-8**). Some battery designs work best when they are warm. For these designs, the battery box also has a heater. Remember, each battery design has its own optimal temperature range.

Heat Shields Some batteries may have a heat shield made of plastic or another material to protect the starting battery from high underhood temperatures. Vehicles equipped for cold climates may have a battery blanket or heater to keep the battery warm during extremely cold weather.

Recycling Batteries

The materials used to make a battery can be used in the future through recycling. Batteries should not be

discarded with regular trash because they contain metals and chemicals that are hazardous to the environment.

CAUTION!

A battery should never be incinerated; doing this can cause an explosion.

In 1994, the Rechargeable Battery Recycling Corporation (RBRC) was established to promote recycling of rechargeable batteries in North America. RBRC is a nonprofit organization that collects batteries from consumers and businesses and sends them to recycling companies. Collected batteries are sorted by their chemical makeup. Then they are broken apart and their elements separated. The chemicals or materials are further separated and then collected.

Ninety-eight percent of all lead-acid batteries are recycled. During the recycling process, the lead, plastic, and acids are separated. The electrolyte (sulfuric acid) can be reused or is discarded after it has been neutralized. The plastic casing is cut into small pieces, scrubbed, and melted to make new battery cases and other parts. The lead is also melted and poured into ingots to be used in new batteries.

BATTERY RATINGS

The voltage rating of a battery may be expressed as open circuit or operating voltage. **Open circuit voltage** is the voltage measured across the battery when there is no load on the battery. Operating voltage is the voltage measured across the battery when it is under a load.

The available current from a battery is expressed as the battery's capacity to provide a certain amount of current for a certain amount of time and at a certain temperature. Basically, a capacity rating expresses how much electrical energy a battery can store.

Ampere-Hour

A commonly used capacity rating is the ampere-hour rating. In the past, this was the common rating method for lead-acid batteries. However, these batteries are now rated otherwise. Other battery designs are still rated in ampere-hours or milliamp-hours.

The **ampere-hour (AH) rating** is the amount of steady current that a fully charged battery can supply for 20 hours at 80°F (26.7°) without the cell's voltage dropping below a predetermined level. For example, if a 12-volt battery can be discharged for 20 hours at a rate of 4.0 amperes before its voltage drops to

10.5 volts, it would be rated at 80 AH (20 hours \times 4 amps = 80 AH). A 100 AH battery will provide 1 amp for 100 hours, or 100 amps for 1 hour.

Watt-Hour Rating

Some battery manufacturers rate their batteries in watt-hours. The **watt-hour rating** is determined at 0°F (−17.7°C) because the battery's capacity changes with temperature. The rating is calculated by multiplying a battery's AH rating by the battery's voltage. The watt-hour rating of a battery may be listed in units of kilowatts. If a battery can deliver 5 AH at 200 volts, it would be rated at 1 kilowatt-hour (5 AH \times 200 volts = 1,000 watt-hour or 1 kilowatt-hour).

Cold Cranking Amps

The **cold cranking amps (CCA)** rating is the common method of rating most automotive starting batteries. It is determined by the load, in amperes, that a battery is able to deliver for 30 seconds at 0°F (−17.7°C) without its voltage dropping below a predetermined level. That voltage level for a 12-volt battery is 7.2 volts. The normal range for passenger car and light truck batteries is between 300 and 600 CCA; some batteries have a rating as high as 1,100 CCA.

Cranking Amps

The **cranking amps (CA) rating** is similar to CCA and is a measure of the current a battery can deliver at 32°F (0°C) for 30 seconds and maintain voltage at a predetermined level. Again, this level is 1.2 volts per cell (7.2 volts) for a 12-volt battery. This rating is more commonly used in climates that are not subject to extremely cold weather. Typically, the CCA rating of a battery is about 20% less than its CA rating.

Reserve Capacity

The **reserve capacity (RC) rating** is determined by the length of time, in minutes, that a fully charged starting battery at 80°F (26.7°C) can be discharged at 25 amperes before battery voltage drops below 10.5 volts. This rating gives an indication of how long the vehicle can be driven with the headlights on if the charging system fails. A battery with a reserve capacity of 120 would be able to deliver 25 amps for 120 minutes before its voltage drops below 10.5 volts.

COMMON TYPES OF BATTERIES

In addition to their use in automobiles, batteries are used in many other applications. As a result, there are many different types and designs of batteries available. Batteries differ in size, from small single cells to large battery packs, comprised of many cells. They

also have different ratings (not always dependent on size) and service lives. The primary difference between batteries is the chemicals used in the cells.

Battery Chemistry

The following battery types can be or are being used in automobiles. Some of the batteries in the list that follows are discussed in more detail later in this chapter.

Lead-Acid Lead-acid batteries are the most commonly used starting battery. This type of battery is rechargeable. Several lead-acid batteries are connected in series to provide high voltage in some electric vehicles. There are many variations to the basic design, but all work and are constructed in the same way. The lead-acid cell has electrodes made of lead and lead-oxide with an electrolyte that is a strong acid. The lead-acid battery is one of the oldest battery designs.

Nickel-Cadmium (NiCad) NiCad batteries are mostly used in portable radios, emergency medical equipment, professional video cameras, and power tools. They provide great power and are normally the battery of choice for power tools. The electrodes in a NiCad cell are nickel hydroxide and cadmium. The electrolyte is potassium hydroxide (**Figure 17-9**). NiCad batteries are economical and have a long service life. However, cadmium is an environmentally unfriendly metal, which is why NiCad batteries are being replaced by other designs.

Nickel-Metal Hydride (NiMH) Nickel-metal hydride batteries are rapidly replacing NiCad batteries

Figure 17-9 The basic construction of a NiCad battery.

because they are more environmentally friendly and are more capable of receiving a full recharge. NiMH batteries also have more capacity than a NiCad but have a reduced service life and a lower current capacity under load. These batteries are commonly used in today's hybrid vehicles. The cells have electrodes made of a metal hydride and nickel hydroxide. The electrolyte is potassium hydroxide.

Sodium-Sulfur (NaS) The electrodes in a sodium-sulfur battery cell are made of molten sodium (negative electrode) and liquid sulfur (positive electrode). The plates are separated by a solid ceramic electrolyte made of aluminum. The battery must be kept at about 570°F (300°C) to discharge and recharge. This design of battery is very efficient and is currently being researched for possible use in vehicles.

Sodium-Nickel-Chloride The electrodes in a sodium-nickel-chloride cell are made with nickel and iron powders and sodium chloride (table salt). The electrodes are separated by a ceramic electrolyte. Sodium-nickel-chloride batteries are also known as “ZEBRA” batteries (**Figure 17-10**). These batteries have nearly five times the energy density as a lead-acid battery and are totally recyclable. However, they must operate at high temperatures, and the required thermal management system greatly raises their production cost. These batteries were designed to be used in automobiles and trains.

Lithium-Ion (Li-Ion) The electrodes in lithium-ion cells are made of a carbon compound (graphite) and a metal oxide. The electrodes are submersed in lithium salt. Overheating these cells may produce pure lithium in the cells. This metal is very reactive and can explode when hot. To prevent overheating, Li-Ion

Figure 17-10 The sodium-nickel-chloride battery, made of nickel and iron powders, sodium chloride, and a ceramic electrolyte, is also known as the “ZEBRA” battery.

cells have built-in protective electronics and/or fuses to prevent reverse polarity and overcharging. Li-Ion batteries have very good power-to-weight ratios and are making their way into hybrid vehicles.

Lithium-Polymer (Li-Poly) The lithium-polymer battery is nearly identical to a Li-Ion battery. Like the Li-Ion, the electrodes are made of a carbon compound (graphite) and a metal oxide. However, the lithium salt electrolyte is held in a thin, solid, plasticlike polymer rather than as a liquid. The solid polymer electrolyte is not flammable; therefore, these batteries are less hazardous if they are mistreated. These batteries can store much more energy than a lead-acid battery. They also offer many other advantages and may be used in hybrid and fuel cell vehicles in the future (**Figure 17-11**).

Nickel-Zinc Nickel-zinc battery cells are also being researched and tested for possible use in vehicles. They have high specific energy and power capability, have good deep cycle capability, can operate within a

Figure 17-11 A chart comparing different battery designs and the main reasons Li-Poly batteries are being heavily researched for use in electric drive vehicles.

wide range of temperatures, are made of abundant low-cost materials, and are environmentally friendly. The nickel-zinc battery is an alkaline rechargeable system. These cells use a nickel/nickel-oxide electrode as the cathode and the zinc/zinc-oxide electrode as the anode. The electrolyte is normally potassium hydroxide.

HIGH-VOLTAGE BATTERIES

To power drive or traction motors, high voltages are necessary. High-voltage battery packs are assemblies of many cells. The cells are one of two configurations: cylindrical or prismatic (**Figure 17-12**). In a **cylindrical cell**, the electrodes are rolled together and fit into a metal cylinder. A **separator** soaked in the electrolyte is placed between the plates. This design requires much storage space. When several cylinders are assembled together, there is much wasted space between the cylinders. **Prismatic cells** do not have this problem. They have flat electrodes placed into a box with separators placed between them. Prismatic cells tend to be more expensive to produce than cylindrical cells. Lead-acid batteries have prismatic cells, and some NiMH batteries found in hybrids are also constructed this way.

Applications

A vehicle equipped with a starter/generator can be considered a mild hybrid and relies on a 42-volt system. Functions such as stop-start, regenerative braking, and electrical assist are common to full and mild hybrid vehicles. However, only full hybrids have the ability to move in an electric-only mode. A full hybrid vehicle may have a battery pack that can supply more than 300 volts. Hybrid vehicles may also have a separate starting battery for the engine (**Figure 17-13**).

The starting battery also is the power source for the lights and other accessories.

Safety Issues

High-voltage circuits in hybrids are identifiable by size and color. The cables have thicker insulation and are colored orange. The connectors are also colored orange. On some vehicles, the high-voltage cables are enclosed in an orange shielding or casing; again the orange indicates high voltage. In addition, the high-voltage battery pack and other high-voltage components have “High Voltage” caution labels. It is important to remember that high voltage is also used to power some vehicle accessories. Always follow the safety precautions given by the manufacturer when working around or with high-voltage systems.

Chapter 6 for a detailed list of battery safety precautions.

LEAD-ACID BATTERIES

The most common automotive batteries are lead-acid designs. The wet cell, gel cell, absorbed glass mat (AGM), and valve regulated are versions of the lead-acid battery.

Basic Construction

A lead-acid battery consists of grids, positive plates, negative plates, separators, elements, electrolyte, a container, cell covers, vent plugs, and cell containers

Figure 17-12 The basic construction of cylindrical and prismatic cells.

Figure 17-13 Location of the batteries in a Honda Civic hybrid.

(Figure 17-14). A **grid** is a lead alloy frame that supports the active material of each plate. Plates are typically flat, rectangular components that are either positive or negative, depending on the active material they hold.

The positive plate has a grid filled with its active material, lead peroxide. **Lead peroxide (PbO_2)** is a dark brown, crystalline material. The material pasted onto the grids of the negative plates is **sponge lead (Pb)**. Both plates are very porous and allow the liquid electrolyte to penetrate freely.

Each battery contains a number of elements. An **element** is a group of positive and negative plates (Figure 17-15). The plates are formed into a plate group, which holds a number of plates of the same polarity. The like-charged plates are welded to a lead alloy post or **plate strap**. The plate groups are placed alternately within the battery—positive, negative, positive, negative, and so on. There is usually one extra set of negative plates to balance the charge. To prevent the different plate groups from touching each other, separators are inserted between them. Separators are porous plastic sheets that allow for a transfer

of ions between plates. When the element is placed into the battery case and immersed in electrolyte, it becomes a cell.

The electrolyte is a solution of sulfuric acid and water. The sulfuric acid supplies sulfate, which chemically reacts with both the lead and PbO_2 to release electrical energy. In addition, the sulfuric acid is the carrier for the electrons as they move inside the battery. To cause the required chemical reaction, the electrolyte must be the correct mixture of water and sulfuric acid. At 12.6 volts, the desired solution is 65% water and 35% sulfuric acid. Available voltage decreases when the percentage of acid in the solution decreases.

Casing Design The container or shell of the battery is usually a one-piece, molded assembly of polypropylene, hard rubber, or plastic. The case has a number of individual cell compartments. Cell connectors are used to join all cells of a battery in series.

The top of the battery is encased by a cell cover. The cover may be a one-piece design, or the cells might have their own individual covers. The cover

Figure 17-14 Components of a typical lead-acid storage battery.

must have vent holes to allow hydrogen and oxygen gases to escape. These gases are formed during charging and discharging. Battery vents can be permanently fixed to the cover or be removable, depending on the design of the battery. Vent plugs or caps are used on some batteries to close the openings in the cell cover and to allow for topping off the cells with electrolyte or water.

At the bottom of some battery casings is a sediment chamber. The chamber collects the materials that fall from the plates. If the sediments do not fall below the plates, they could cause a short between the plates. Some batteries do not have a sediment chamber; rather the separators are used to contain all sediments and keep them from contacting the plates.

CAUTION!

When lifting a battery, excessive pressure on the end walls could cause acid to spew through the vent caps, resulting in personal injury. Lift with a battery carrier or with your hands on opposite corners.

Terminals The battery has two external terminals: a positive (+) and a negative (−). These terminals are

Figure 17-15 The parts of a typical battery element.

two tapered posts, “L” terminals, threaded studs on top of the case, or two internally threaded connectors on the side (**Figure 17-16**). The terminals have either a positive (+) or a negative (−) marking, depending on which end of the series they represent.

The size of the tapered terminals is specified by standards set by the **Battery Council International (BCI)** and Society of Automotive Engineers (SAE).

Figure 17-16 The most common types of automotive battery terminals. Courtesy of Ford Motor Company

This means that all positive and negative cable clamps will fit any corresponding battery terminal, regardless of the battery's manufacturer. The positive terminal is slightly larger, usually around $\frac{1}{16}$ inch in diameter at the top, whereas the negative terminal usually has a $\frac{5}{16}$ -inch diameter. This minimizes, but does not prevent, the danger of installing the battery cables in reverse polarity.

Side terminals are positioned near the top of the battery case. These terminals are threaded and require a special bolt to connect the cables. Some batteries are fitted with both top and side terminals to allow them to be used in many different vehicles.

Discharging and Charging

The chemical reaction between the active materials on the positive and negative plates and the electrolyte releases electrical energy. When a battery discharges (**Figure 17-17**), lead in the lead peroxide of the positive plate combines with the sulfate radical (SO_4) to form lead sulfate (PbSO_4).

A similar reaction takes place at the negative plate. The lead (Pb) of the negative active material combines

with sulfate radical (SO_4) to also form lead sulfate (PbSO_4), a neutral and inactive material. Therefore, lead sulfate forms at both plates as the battery discharges.

During this chemical reaction, the oxygen from the lead peroxide and the hydrogen from the sulfuric acid combine to form water (H_2O). As discharging takes place, the electrolyte becomes weaker and the positive and negative plates become like one another.

The recharging process (**Figure 17-18**) is the reverse of discharging. Electricity from an outside source, such as the vehicle's generator or a battery recharger, is forced into the battery. The lead sulfate (PbSO_4) on both plates separates into lead (Pb) and sulfate (SO_4). As the sulfate (SO_4) leaves both plates, it combines with hydrogen in the electrolyte to form sulfuric acid (H_2SO_4). At the same time, the oxygen (O_2) in the electrolyte combines with the lead (Pb) at the positive plate to form lead peroxide (PbO_2). As a result, the negative plate returns to its original form of lead (Pb), and the positive plate reverts to lead peroxide (PbO_2).

Figure 17-17 Chemical action that occurs inside a battery during a discharge cycle.

Figure 17-18 Chemical action inside a battery during the charge cycle.

Figure 17-19 A battery with removable cell caps.

An unsealed battery gradually loses water due to its conversion into hydrogen and oxygen; these gases escape the battery through the vent caps (**Figure 17-19**). If the lost water is not replaced, the level of the electrolyte falls below the tops of the plates. This results in a high concentration of sulfuric acid in the electrolyte and permits the uncovered material of the plates to dry and harden. This will reduce the service life of a battery. This is why the electrolyte level in the battery must be frequently checked.

Designs

Lead-acid batteries can be designed as a starting battery or a deep cycle battery. Deep cycle batteries are designed to go through many charge and discharge cycles. They have thicker and fewer plates than a starting battery. The exact chemical composition of lead-acid batteries also depends on the designed purpose of the battery. However, all lead-acid batteries are based on the reaction of lead and acid.

Maintenance-Free and Low-Maintenance Batteries The majority of batteries installed in today's

Calcium or strontium alloy. . .

- Adds strength
- Cuts gassing up to 97%
- Resists overcharge

Figure 17-20 Maintenance-free battery grids with support bars give increased strength and faster electrical delivery. Courtesy of Ford Motor Company

vehicles are low-maintenance or maintenance-free designs. A low-maintenance battery is a heavy-duty version of a normal lead-acid battery. Many of the parts are thicker and made with different, more durable materials. Low-maintenance batteries have vent holes and caps, which allow water to be added to the cells. However, a low-maintenance battery requires additional water substantially less often than a conventional battery.

Similar in construction but made with different plate materials, a **maintenance-free battery** experiences little gassing during discharge and charge cycles (**Figure 17-20**). Therefore, maintenance-free batteries do not have external holes or caps (**Figure 17-21**). They are equipped with small gas vents that prevent gas pressure buildup in the case. Water is never added to maintenance-free batteries.

Hybrid Batteries A **hybrid battery** can withstand six deep cycles and still retain 100% of its original reserve capacity. A battery experiences a deep cycle when it is near totally discharged and then recharged. The grid construction differs from other batteries in that the

Figure 17-21 Construction of a maintenance-free battery showing the location of the gas vents.

plates have a lug located near the center of the grid. In addition, the vertical and horizontal grid bars are arranged in a radial design. With this design, current has less resistance and a shorter path to follow. This means the battery is capable of providing more current at a faster rate.

The separators are constructed of glass covered with a resin or fiberglass. The glass separators offer low electrical resistance with high resistance to chemical contamination.

Recombination Batteries A recombination or **recombinant battery** is a completely sealed maintenance-free battery that uses a gel-type electrolyte. In a gel cell battery, gassing is minimized and vents are not needed. During charging, the negative plates never reach a fully charged condition and therefore cause little or no release of hydrogen. Oxygen is released at the positive plates, but it passes through the separators and recombines with the negative plates.

Absorbed Glass Mat Batteries The electrolyte in **absorbed glass mat (AGM) batteries** is held in moistened fiberglass matting. The matting is sandwiched between the battery's plates, where it doubles as a vibration dampener. AGM batteries are recombinant batteries.

Rolls of high-purity lead plates are tightly compressed into six cells (**Figure 17-22**). The plates are separated by acid-permeated vitreous separators. Vitreous separators absorb acid in the same way a paper towel absorbs water. Each of the cells is enclosed in its own cylinder within the battery case, forming a sealed, closed system that resembles a six-pack of soda. During normal use, hydrogen and oxygen within the battery are captured and recombined to

Figure 17-22 The construction of an AGM battery. Courtesy of Exide Technologies

form water within the electrolyte. This eliminates the need to ever add water to the battery.

The spiral rolled plates and fiberglass mats are virtually impervious to vibration and impact. AGM batteries will never leak, have short recharging times, and have low internal resistance, which provides increased output.

Valve-Regulated Batteries **Valve-regulated lead-acid (VRLA) batteries** are similar to AGM batteries and are recombinant batteries. The oxygen produced on the positive plates is absorbed by the negative plate. That, in turn, decreases the amount of hydrogen produced at the negative plate. The combination of hydrogen and oxygen produces water, which is returned to the electrolyte. Therefore, this battery never needs to have water added to its electrolyte mixture.

One plate in a VRLA is made of a lead-tin-calcium alloy with porous lead dioxide; the other is also made of a lead-tin-calcium alloy but has spongy lead as the active material. The electrolyte is sulfuric acid that is absorbed into plate separators made of a glass-fiber fabric. The battery is equipped with a valve that opens to relieve any excessive pressure that builds up in the battery. At all other times the valve is closed and the battery is totally sealed.

Factors Affecting Battery Life

All storage batteries have a limited service life, but many conditions can decrease it.

Improper Electrolyte Levels With nonsealed batteries, water should be the only portion of the electrolyte lost due to evaporation during hot weather and gassing during charging. Maintaining an adequate electrolyte level is the basic step in extending battery life for these designs.

Temperature Batteries do not work well when they are cold. At 0°F (−17.8°C) a battery is only capable of working at 40% of its capacity. There is also the possibility of the battery freezing when it is very cold and its charge is low. When the battery is allowed to get too hot, the water in the electrolyte can evaporate. Batteries used in hot climates should have their electrolyte level checked very frequently and only distilled water should be added if necessary.

Corrosion Battery corrosion is commonly caused by spilled electrolyte or electrolyte condensation from gassing. In either case, the sulfuric acid corrodes, attacks, and can destroy not only connectors and terminals but holddown straps and the battery tray as well.

Corroded connections increase resistance at the battery terminals, which reduces the applied voltage to the vehicle's electrical system. Corrosion on the battery cover can also create a path for current, which can allow the battery to slowly discharge. Finally, corrosion can destroy the holddown straps and battery tray, which can result in physical damage to the battery and/or vehicle.

Overcharging Batteries can be overcharged by either the vehicle's charging system or a battery charger. In either case, the result is a violent chemical reaction within the battery that causes a loss of water in the cells. This can permanently reduce the capacity of the battery. Overcharging can also cause excessive heat, which can oxidize the positive plate grid material and even buckle the plates, resulting in a loss of cell capacity and early battery failure.

Undercharge/Sulfation The vehicle's charging system might not fully recharge the battery due to a fault in the charging system. This causes the battery to operate in a partially discharged condition. A battery in this condition will become sulfated when the sulfate normally formed in the plates becomes dense, hard, and chemically irreversible. This happens because the sulfate has been allowed to remain in the plates for a long period.

Sulfation of the plates causes two problems. First, it lowers the specific gravity levels of the electrolyte and increases the danger of freezing. Second, in cold

weather, a sulfated battery often fails to crank the engine because of its lack of reserve power.

Poor Mounting Loose or missing holddown straps allow the battery to vibrate or bounce during vehicle operation. This can shake the active materials off the grid plates, severely shortening battery life. It can also loosen the plate connections to the plate strap, loosen cable connections, or even crack the battery case.

Cycling Heavy and repeated cycling can cause the positive plate material to break away from its grids and fall into the sediment chambers at the base of the case. This problem reduces battery capacity and can lead to premature short circuiting between the plates. Fortunately, the new envelope design found in many batteries reduces this problem.

SERVICING AND TESTING BATTERIES

CAUTION!

Always wear safety glasses or goggles when working with batteries. When a battery is charging or discharging, it gives off highly explosive hydrogen gas. Some hydrogen gas is present in the battery at all times. Any flame or spark can ignite this gas, causing the battery to violently explode, propelling the vent caps at a high velocity and spraying acid in a wide area. Sulfuric acid can cause severe skin burns. If electrolyte contacts your skin or eyes, flush the area with water for several minutes. When eye contact occurs, force your eyelid open and flush your eyes with eyewash solution. Do not rub your eyes or skin and call a doctor immediately.

Testing batteries is an important part of electrical system service. Prior to conducting any tests, make sure the battery is fully charged. Also remove the surface charge of the battery by turning on the headlights with the engine off. Keep the lights on for at least 3 minutes. Poor and inaccurate tests can lead to serious problems and expensive and unneeded repairs. Depending on the design of the battery, state of charge and capacity can be determined in several ways: specific gravity tests, visual inspection of batteries with a built-in hydrometer, open circuit voltage tests, and the capacity test.

Figure 17-23 Batteries should be carefully checked for damage, dirt, and corrosion.

Inspection

Testing a lead-acid battery should begin with a thorough inspection of the battery and its terminals (**Figure 17-23**). The following items should be checked:

1. Check the age of the battery by looking at the date code on the battery.
2. Check the condition of the case. A damaged battery should be replaced.
3. If the battery is not sealed, check the electrolyte levels in all cells and correct them as necessary. If water is added, charge the battery before conducting any test on the battery.
4. Check the condition of the battery terminals and cables. Clean any corrosion from the cable ends and terminals. Make sure the cable ends are tightly fastened to the terminals.
5. Make sure the battery holdowns are holding the battery securely in place.

Figure 17-24 Performing a battery leakage test.

positive lead across the top and sides of the battery case (**Figure 17-24**). If some voltage is read on the meter, current is leaking out of the battery. The battery should be cleaned and then rechecked. If voltage is again measured, the battery should be replaced; the case is porous or cracked.

Cleaning the Battery and Terminals

Before removing the battery connectors or the battery, always neutralize any accumulated corrosion on terminals, connectors, and other metal parts. Apply a solution of baking soda and water or ammonia and water. Do not splash the corrosion onto the vehicle's paint, metal or rubber parts, or onto your hands and face. Be sure the solution cannot enter the battery cells. A stiff-bristle brush is ideal for removing heavy buildup. Dirt and accumulated grease can be removed with a detergent solution or solvent. After cleaning, rinse the battery and cable connections with clean water. Dry the components with a clean rag or low-pressure compressed air.

SHOP TALK

Remember to connect a memory saver and obtain security codes for the vehicle before disconnecting the battery.

To clean the inside surfaces of the connectors and the battery terminals, remove the cables. Always begin with the ground cable. Spring-type cable connectors are removed by squeezing the ends of their prongs together with wide-jaw, vise-gripping, channel lock, or battery pliers. This pressure expands the connector so it can be lifted off the terminal post.

For connectors tightened with nuts and bolts, loosen the nut using a box-end wrench and/or cable-clamp pliers (**Figure 17-25**). Using ordinary pliers or an open-end wrench can cause problems. These tools

Chapter 7 for lead-acid battery inspection, maintenance, and cleaning procedures.

Battery Leakage Test

To perform a battery leakage test, set a voltmeter to a low DC volt range. Connect the negative lead to the battery's negative post. Then move the meter's

Figure 17-25 It is best to loosen a battery clamp with a box-end wrench and/or cable-clamp pliers.

might slip off under pressure with enough force to break the cell cover or damage the casing.

Always grip the cable while loosening the nut. This reduces the pressure on the terminal post that could break it or loosen its mounting in the battery. If the connector does not lift easily off the terminal when loosened, use a clamp puller. Prying with a screwdriver or bar strains the terminal post and the plates attached to it. This can break the cell cover or pop the plates loose from the terminal post.

Once the connectors have been removed, open the connector using a connector-spreading tool. Neutralize any remaining corrosion by dipping it in a baking soda or ammonia solution. Next, clean the inside of the connectors and the posts using a wire brush with external and internal bristles (Figure 17-26).

Begin reinstallation by expanding the opening of the clamp (Figure 17-27) so that force is not needed to place it over the post. Then position and tighten the

Figure 17-27 Before reinstalling the cable end onto the battery, use terminal end expanders to make sure the end does not need to be forced onto the battery post.

terminal on its post. Do not overtighten any nuts or bolts; this could damage the post or terminal.

Battery Hydrometer

The electrolyte of a fully charged battery is usually about 64% water and 36% sulfuric acid. This corresponds to a specific gravity of 1.270. **Specific gravity** is the weight of a given volume of any liquid divided by the weight of an equal volume of water. Pure water has a specific gravity of 1.000, whereas battery electrolyte should have a specific gravity of 1.260 to 1.280 at 80°F (26.7°C). In other words, the electrolyte should be 1.260 to 1.280 times heavier than water.

The specific gravity of the electrolyte decreases as the battery discharges. This is why measuring the specific gravity of the electrolyte with a hydrometer can be a good indicator of how much charge a battery has lost (Figure 17-28). Hydrometer readings should not vary more than 0.05 difference between cells. More variance is an indication that the battery is bad.

Figure 17-26 Combination external/internal wire brushes clean both terminals and inside cable connector surfaces.

Figure 17-28 A graph showing the relationship between specific gravity, open circuit voltage, and the state of charge of a battery cell.

Figure 17-29 (A) When the scale sinks in the electrolyte, the specific gravity is low; (B) when it floats high, the specific gravity is high.

The electrolyte's specific gravity can be measured on unsealed batteries to give a fairly good indication of the battery's state-of-charge (SOC). A basic battery hydrometer uses a glass float or hydrometer in a glass tube to measure the electrolyte's specific gravity. Squeezing the hydrometer's bulb pulls electrolyte into the tube. When filled with test electrolyte, the hydrometer float bobs in the electrolyte. The depth at which the float sinks in the electrolyte indicates its relative weight compared to water. The reading is taken off the scale by sighting along the level of the electrolyte. If the hydrometer floats deeply in the electrolyte, the specific gravity is low (**Figure 17-29A**). If the hydrometer floats high in the electrolyte, the specific gravity is high (**Figure 17-29B**).

Because temperature affects the specific gravity of a substance, the specific gravity reading should be corrected by adding or subtracting 4 points (0.004) for each 10°F (−10°C), above or below the standard of 80°F (26.7°C). Most hydrometers have a built-in thermometer to measure the temperature of the electrolyte (**Figure 17-30**). The hydrometer reading can be misleading if it is not adjusted. For example, a reading of 1.260 taken at 20°F (−6.6°C) would be $1.260 - (6 \times 0.004 \text{ or } 0.024) = 1.236$. This lower reading means the cell has less charge than indicated. The specific gravity of the cells of a fully charged battery should be near 1.265 when corrected for electrolyte temperature. Recharge any battery if the specific gravity drops below an average of 1.230.

Refractometer In many cases, the same refractometer used to test engine coolant can be used to check the specific gravity of electrolyte. These tools also feature automatic temperature compensation. A refractometer uses a prism to analyze fluids.

Built-In Hydrometers

On some maintenance-free batteries, a special temperature-compensating hydrometer is built into

Figure 17-30 Hydrometers with thermometer correction scales make adjusting for electrolyte temperature easy.

Figure 17-31 Sight glass in a maintenance-free battery.

the battery case (**Figure 17-31**). A quick visual check indicates the battery's SOC (**Figure 17-32**). It is important when observing the hydrometer that the battery has a clean top to see the correct indication. A flashlight may be required in poorly lit areas. Always look straight down when viewing the hydrometer.

A few battery designs have a charge indicator on the top of the case (**Figure 17-33**). These batteries use a color display to note the SOC. Typically, green means "OK," gray means "Check for recharge," and white means "Change or replace."

Many batteries do not have a built-in hydrometer. A voltage check is the only way to check the battery's SOC. The specific gravity of these batteries cannot be checked because the batteries are sealed. Never pry the cell caps off to check the electrolyte; leave the battery sealed.

Figure 17-32 Design and operation of built-in hydrometers on maintenance-free sealed batteries.

Figure 17-33 A battery with a built-in charge indicator. Courtesy of Robert Bosch GmbH, www.bosch-presse.de

Open Circuit Voltage Test

An open circuit voltage check can be used as a substitute for the hydrometer specific gravity test on maintenance-free sealed batteries with no built-in hydrometer. As the battery is charged or discharged, slight changes occur in the battery's voltage. Therefore, battery voltage with no load applied can give some indication of the SOC.

The battery's temperature should be between 60° and 100°F (15.5° and 37.7°C). The voltage must be allowed to stabilize for at least 10 minutes with no load applied. On vehicles with high drains (computer controls, clocks, and accessories that always draw a small amount of current), it may be necessary to disconnect the battery ground cable. On batteries that have just been recharged, apply a heavy

Figure 17-34 Measuring open circuit voltage across battery terminals using a voltmeter.

load for 15 seconds to remove the surface charge, then allow the battery to stabilize. Once voltage has stabilized, use a digital voltmeter to measure the battery voltage to the nearest one-tenth of a volt (**Figure 17-34**). A fully charged 12-volt battery should have a terminal voltage of 12.6 volts. However, sealed AGM and gel cell batteries may have a slightly higher voltage (12.8–12.9 volts). Use Figure 17-28 to interpret the results. As you can see, minor changes in battery open circuit voltage can indicate major changes in SOC. If the test indicates an SOC below 75%, recharge the battery and perform the capacity test to determine battery condition.

Battery Load Test

The **load** or **capacity test** determines how well a battery performs under a load. It determines the battery's ability to furnish starting current and still maintain sufficient voltage to operate other systems. A battery load tester (**Figure 17-35**) or a volt/ampere tester (VAT) can be used for this test. A VAT can be

Figure 17-35 A battery load tester.

Figure 17-36 A typical automatic VAT. Courtesy of SPX Service Solutions

used to test batteries, starting systems, and charging systems. Both testers have a voltmeter, an ammeter, and a carbon pile. The carbon pile is a variable resistor. When the tester is attached to the battery and operated, the carbon pile will draw current from the battery. The ammeter will read the amount of current draw. The maximum current draw from the battery, with acceptable voltage, is compared to the rating of the battery to see if the battery is okay.

Some battery load testers and VATs automatically adjust the load or carbon pile. Battery information is inputted into these machines and it does the rest (**Figure 17-36**).

The load or capacity test can be performed with the battery either in or out of the vehicle. The battery must be at or very near a full SOC. Use the specific gravity test or open circuit voltage test to determine the SOC, and recharge the battery if needed. For best results, the electrolyte should be as close to 80°F (26.7°C) as possible. Cold batteries show considerably lower capacity. Never load test a sealed battery if its temperature is below 60°F (15.5°C). Photo Sequence 14 shows the correct way to use a VAT-40 to conduct a load test.

During a load test, a load that simulates the current draw of a starting motor is put on the battery. The amount of current draw is determined by the rating of the battery and the battery's voltage is observed for 15 seconds.

When performing a battery load test, follow these guidelines:

- Make sure that the inductive pickup surrounds all of the wires from the battery's negative terminal.

Figure 17-37 Adapters may be needed to test and change batteries with side-mount terminals.

- Observe the correct polarity and make sure that the test leads are making good contact with the battery posts.
- If the tester is equipped with an adjustment for battery temperature, set it to the proper setting.
- To test the battery, turn the load control knob to draw current at the rate of three times the battery's ampere-hour rating or one-half of its CCA rating.
- Discontinue the load after 15 seconds.

SHOP TALK

On some batteries with side terminals, obtaining a sound connection for the tester can be a problem. The best solution is to use the appropriate adapter (**Figure 17-37**). If an adapter is not available, use a $\frac{3}{8}$ -inch coarse bolt with a nut on it. Bottom out the bolt. Back it off a turn. Then tighten the nut against the contact. Now attach the lead to the nut.

Interpreting Results If the voltage reading exceeds 10.5 volts, the battery is supplying sufficient current with a good margin to safety. If the reading is right on the spec, the battery might not have the reserve necessary to handle cranking during low temperatures.

After the load is turned off, if the voltage reads below the minimum, watch the voltmeter. If it rises above 12.4, the battery is bad—it can hold a charge but cannot supply the required current. The battery can be recharged and retested, but the results are likely to be the same.

If the voltage tests below the minimum and the voltmeter does not rise above 12.4 when the load is removed, the problem may only be a low SOC. Recharge the battery and load test again.

Battery Capacitance Test

Many manufacturers recommend that a **capacitance** or **conductance test** be performed on batteries. Conductance describes a battery's ability to conduct current. It is a measurement of the plate surface

Conducting a Battery Load Test

P14-1 To conduct this test, you need a VAT-40 or similar equipment. Before conducting the test, make sure the battery is fully charged.

P14-2 Check the markings on the battery to identify its CCA rating. This battery has a rating of 630 CCA.

P14-3 Check the temperature of the battery; it should be around 70°F (21°C).

P14-4 Attach the tester's battery leads to the correct terminals on the battery.

Conducting a Battery Load Test (*continued*)

P14-5 Clamp the tester's inductive lead around the tester's negative cable. Normally the arrow on the clamp should face away from the negative post of the battery.

P14-6 Turn the "Zero Adjust" knob on the tester until the ammeter reads zero.

P14-7 Rotate the load control until the ammeter reads one-half of the battery's CCA rating, which in this case is 315 amps.

P14-8 After 15 seconds, read the voltage of the battery and turn the load control off. Then disconnect the tester's leads.

available in a battery for chemical reaction. Measuring conductance provides a reliable indication of a battery's condition and is correlated to battery capacity. Conductance can be used to detect cell defects, shorts, normal aging, and open circuits, which can cause the battery to fail.

A fully charged new battery will have a high conductance reading anywhere from 110% to 140% of its CCA rating. As a battery ages, the plate surface can sulfate or shed active material, which will lower its capacity and conductance. A conductance test is the only test that will yield accurate measurements of a battery with low SOC.

When a battery has lost a significant percentage of its cranking ability, the conductance reading will fall well below its rating and the test decision will be to replace the battery. Because conductance measurements can track the life of the battery, they are also effective for predicting end of life before the battery fails.

To measure conductance, the tester (Figure 17-38) creates a small signal that is sent through the battery and then measures a portion of the AC current

response. The tester displays the service condition of the battery. The tester will indicate that the battery is good, needs to be recharged and tested again, has failed, or will fail shortly.

Many conductance testers will display a code at the end of the test. Be sure to look up this code in the operating manual before taking any action in response to the test results.

SHOP TALK

When testing an AGM battery with a typical capacitance tester, add 100 to the CCA rating of the battery when asked to enter the rating by the tester. If this is not done, all test results will be wrong.

Chapter 6 for a detailed list of battery safety precautions.

Figure 17-38 A conductance (capacitance) battery tester.

Battery Drains

Many of today's vehicles have **parasitic loads**. Parasitic loads are current drains that exist when the key is off. This drain is caused by systems that operate when the engine is not running. A parasitic load is normal unless it exceeds specifications. These drains can cause a battery to lose its charge overnight or after a few days (Table 17-1). The drains can also deplete the battery and cause various driveability problems. The

TABLE 17-1 A LOOK AT HOW LONG IT TAKES DIFFERENT CURRENT DRAINS TO DROP A TYPICAL BATTERY'S STATE-OF-CHARGE (SOC) TO 50%.

Constant Current Drain	50% SOC IN:
25 mA	30½ Days
50 mA	16½ Days
100 mA	8¼ Days
250 mA	3¼ Days
500 mA	1½ Days
750 mA	1 Day
1 A	19 Hours
2 A	12 Hours

computer may go into its back-up mode, set false codes, or raise idle speeds to compensate for the low battery voltage. A constantly low battery will also have a shortened service life.

Most manufacturers have a specification for the maximum allowable amount of parasitic drain. All vehicles will have some because small amounts of current are needed to maintain the memory in various systems. A drain of 30 mA is normal for most. This will not cause a battery to lose its charge quickly. Excessive current drains are caused by problems and they will run down a battery. The most common cause is a light that is not turning off—such as the glove box, trunk, or engine compartment light. The problem can also be in an electronic system. Many of these systems are designed to periodically monitor conditions; these episodes are called wake-up times. If an electronic unit wakes up but does not shut down soon afterward, it is malfunctioning and will drain the battery.

When a battery quickly loses its charge, a battery drain test should be conducted. The current drain can be measured with a DMM connected in series with the negative battery cable or by placing a low current probe around the cable. Current drain can also be measured with a high-current tester, such as a VAT. This requires the installation of a multiplying coil between the negative battery cable and the battery terminal post (**Figure 17–39**). The tester's inductive probe is placed around the multiplying coil.

SHOP TALK

Remember to connect a memory saver before disconnecting the battery.

Figure 17–39 Using a multiplying coil to obtain accurate readings when measuring parasitic drains with a VAT-40 or similar tester.

PROCEDURE

To measure the parasitic drains on a battery:

1. Make sure the ignition is off and the key is out of the switch.
2. Turn off all accessories.
3. Place the ignition switch and all vehicle accessories in the off position. Some manufacturers recommend to wait 20 minutes after the ignition is off before testing.
4. Disconnect the underhood lamp, if equipped.
5. Set the DMM to read DC amps.
6. Zero the ammeter.
7. Place the probe around the negative battery cable or insert the meter in series with the cable.
8. Read the ammeter.
9. If the parasitic load is under 2 amps, change the DMM to read mAmps.
10. Read the ammeter.
11. If the parasitic drain is more than the specified maximum, check the trunk, glove box, and interior lights to see if they are on.
12. If a light was on, remove the bulb and watch the battery drain. If the drain is now okay, check that circuit.
13. If the cause of the drain is not the lights, find the problem circuit by removing one fuse at a time while watching the ammeter. The reading will drop when the fuse on the bad circuit is removed.
14. Test the components of that circuit to identify the cause of the drain.

Sometimes excessive battery drain will not be measured at the time of the test. If the battery runs down quickly and has passed all other tests, it may be necessary to monitor the drain overnight. Doing this will verify any problems related to the wake-up modes in the various systems. To do this, use the MIN/MAX feature of the DMM and monitor the parasitic drain overnight.

Battery Cables

Sometimes a battery's performance is affected by its cables. Poor connections and corrosion at the terminals and cable ends will cause voltage drops, which will reduce the available voltage at all of the vehicle's systems. A visual inspection may locate these problems but a voltage drop test across the connections is the best way to identify this problem. Heavily corroded terminals (**Figure 17–40**) are obvious, but sometimes corrosion forms a nearly invisible barrier between the battery terminals and cables. This can be unwanted resistance and will prevent the proper amount of current and voltage from going where they should.

Figure 17-40 Corroded battery terminals reduce the efficiency of the battery and cause voltage drops.

The terminals may also be out of shape, loose, or damaged; these will cause excessive resistance. All battery cables should be inspected and tested for excessive voltage drops. All voltage drop tests should be done under a load. Operate a high-current system while measuring the voltage drop. In most cases, running the starter motor is the best load. Allow a drop of 0.1 volt for each cable connection; a total voltage drop across all battery connections should not exceed 0.2 volt.

Battery Chargers

Battery chargers are designed to supply a constant voltage or a constant current, or a mixture of the two. Constant voltage chargers provide a specific amount of voltage to the battery. The current varies with voltage of the battery. When the potential difference between the charger's voltage and the battery's voltage is great, the current is high. As the battery charges, its voltage increases and the charging current drops off. A constant current charger varies the voltage applied to the battery in order to maintain a constant current.

Both of these techniques work fine as long as the temperature of the battery is maintained. Some chargers have a thermometer to monitor battery temperature. These chargers reduce the charging voltage and/or current in response to rising temperatures.

There are many battery chargers that are “smart” or “intelligent.” These chargers are designed to charge a battery in three basic steps: bulk, absorption, and float. During bulk charging, current is sent to the battery at a maximum safe rate until the voltage reaches approximately 80% of its capacity. Once the battery reaches that voltage level, the charger begins the absorption step. During this time, charging voltage is held constant while the current changes according to the battery's voltage. Once the battery is fully charged,

the charger switches to the float step. During this step, the charger supplies a constant voltage equal to slightly more than the voltage of the battery. The current flow is very low. This step is a maintenance charge and is intended to keep a battery charged while it is not being used.

Chargers can also be designed to supply voltage and current to a battery according to the needs of the vehicle and, often, the needs of the customer. **Fast charging** quickly charges a battery. These supply large amounts of voltage and current. Although this charges the battery quickly, it also can overheat it if it is not closely monitored. This technique is best used when a battery is low on charge and will be installed into the vehicle in a short time. Batteries must be in good condition to accept a fast charge. Sulfation on the plates of the battery can lead to excessive gassing, boiling, and heat buildup during fast charging. Never fast-charge a battery that shows evidence of sulfation buildup or separator damage.

Slow or trickle charging applies low current to the battery and takes quite some time to fully charge it. However, it is unlikely that the battery will overheat and the battery has a good chance to be completely charged. Slow charging is the only safe way of charging sulfated batteries. The chemicals used in the construction of the battery should always be considered before fast charging or slow charging a battery.

Always charge a battery in a well-ventilated area away from sparks and open flames. The charger should be off before connecting or disconnecting the leads to the battery (**Figure 17-41**). Remember to wear eye protection, and never attempt to charge a frozen battery.

All battery chargers have manufacturer-specific characteristics and operating instructions that must be followed. When charging a battery in the vehicle,

Figure 17-41 Careless use of a battery charger caused this battery to explode.

Figure 17-42 Battery sticker with identification and warnings.

always disconnect the battery cables to avoid damaging the generator or other electrical parts.

CAUTION!

Do not exceed the manufacturer's battery-charging limits. Also never charge the battery if the built-in hydrometer is clear or light yellow. Replace the battery.

Replacing a Battery

When a battery needs to be replaced, several things need to be considered when selecting the new battery: its capacity, ratings, and size. Make sure the new battery meets or exceeds the power requirement of the vehicle. The battery needs to fit the battery holding fixtures in the vehicle. The height of the battery is also important. The top of the battery and its terminals must fit safely under the hood without the possibility of shorting across the terminals. BCI group numbers are normally listed on the battery (Figure 17-42) and are used to state its physical size and rating.

NICKEL-BASED BATTERIES

Two types of nickel-based rechargeable batteries are commonly used: the **nickel-metal hydride (NiMH)** and **nickel-cadmium (NiCad)**. Except for the materials used as the anode, a NiMH cell is constructed in the same way as a NiCad cell. The cell voltage from both designs is 1.2 volts, which makes them potentially interchangeable. Most of today's hybrid vehicles use NiMH batteries.

NiMH batteries have replaced NiCad batteries in many applications because of their higher energy densities (more energy is available for a given amount of space), and they use environmentally friendly

metals. Cadmium is considered to be harmful to the environment.

NiCad batteries also suffer from something called the "memory effect." This problem occurs when a battery is not fully discharged and then recharged. If the battery is consistently being recharged after it is only partially discharged, 50%, for example, the battery will eventually only accept and hold a 50% charge. NiMH batteries tend not to be affected by the memory effect.

Nickel-Metal Hydride Cells

NiMH cells are available in the cylindrical and prismatic designs. Both are used in hybrid vehicles. The prismatic design (Figure 17-43) requires less storage space but has less energy density than the cylindrical design (Figure 17-44).

Figure 17-43 A high-voltage battery pack made with prismatic cells. Courtesy of Toyota Motor Sales, U.S.A., Inc.

HV battery module

Figure 17-44 A high-voltage battery module made of several cylindrical battery cells.

These cells are still being studied and developed to overcome some of their weaknesses or limitations. They have a relatively short service life; however, most batteries used in hybrid vehicles have an 8-year warranty. Service life is reduced by subjecting the battery to many deep cycles of charging and discharging. NiMH cells generate high heat while being charged.

Chemical Reactions NiMH batteries have a positive plate that contains nickel hydroxide. The negative plate is made of hydrogen-absorbing metal alloys. The plates are separated by a sheet of fine fibers saturated with an aqueous and alkaline electrolyte—potassium hydroxide. The components of the cell are typically placed in a metal housing and the unit sealed. There is a safety vent that allows high pressures to escape, if needed.

The most commonly used hydrogen-absorbing alloys are compounds of titanium, vanadium, zirconium, nickel, cobalt, manganese, and aluminum. An alloy formed by the combination of two or three of these metals has the ability to absorb and store hydrogen. The amount of hydrogen that can be stored is many times greater than the actual volume of the alloy.

When an NiMH cell discharges, hydrogen moves from the negative to the positive plate (**Figure 17-45**). The electrolyte has no active role in the chemical reaction; therefore, the electrolyte level is not changed by the reaction. When the cell is recharged, hydrogen moves from the positive to negative electrode.

Characteristics There are certain characteristics of NiMH cells that must be understood and remembered, especially for diagnostic purposes and safety.

- NiMH batteries do not store well for long lengths of time, so if the vehicle has not been driven for a while, the battery may lose quite a bit of its normal capacity.
- These batteries have a limited number of charging cycles.

Figure 17-45 The chemical action inside an NiMH cell when it is discharging and charging.

- All hybrids charge the battery while the vehicle is driven.
- The capacity of NiMH batteries decreases with an increase in heat.
- If the battery is exposed to intense heat, it is possible that hydrogen will be released from the battery, and hydrogen can be explosive when introduced to flame or sparks.
- The cells contain an electrolyte comprised mostly of potassium hydroxide. Exposure to the electrolyte can cause skin/eye irritation and or burns.
- The battery packs are very heavy.
- Used batteries should be disposed of according to local and federal laws.

Whenever a battery pack, cooling system components (**Figure 17-46**), or other hybrid parts must be removed, serviced, and/or replaced, always follow the specific procedures given by the manufacturer. If these are not followed exactly, injury to you, the vehicle, and others can result.

Recharging Recharging the high-voltage battery pack is best done by the vehicle itself; however, there are times when it may be necessary to recharge the battery in the shop. Doing so is not a typical procedure. Chances are your shop will not have the correct charger. For example, Toyota hybrid batteries require a special charger that is not sold to its dealerships (**Figure 17-47**). If there is a need for one, the dealership must contact the regional office and have one delivered, and only someone from that office is allowed to operate it. This charger has the normal connections plus a cable to power the battery's cooling system. The charger is designed to bring the battery pack to a 40% to 50% SOC within 3 hours. This is enough to start the vehicle and allow the engine to bring the battery back to full charge.

Figure 17-46 An assembly comprised of various hybrid parts plus the battery.

Figure 17-47 The high-voltage battery charger for Toyota hybrids. There are two output cables: one for the battery pack and the other operates the 12 V system for the battery cooling fans and computer.

Nickel-Cadmium Cells

NiCad (also referred to as NiCd) cells are commonly used in many appliances and may have a future in electric drive vehicles. They have a number of advantages over NiMH cells. One of these advantages is that they can withstand many deep cycles, about three times as many as NiMH cells. NiCad batteries can be produced at relatively low costs and have a long shelf and service life. NiCad batteries are especially good performers when high-energy boosts are required. Most NiCad batteries are of the cylindrical design.

On the downside, NiCad batteries have toxic metals, suffer from the memory effect, have low energy densities, and require charging after they have been unused for a while.

Chemical Reactions NiCad batteries use a nickel hydroxide positive electrode. This plate is made of a fiber mesh. The anode or negative plate is also made of fiber. The plate is covered with cadmium. An alkaline electrolyte, aqueous potassium hydroxide (KOH), serves as a conductor of ions and has only a slight role in the chemical reaction. During discharge, ions leave the anode and move to the cathode. During charging, the opposite occurs.

LITHIUM-BASED BATTERIES

Rechargeable lithium-based batteries are very similar in construction to nickel-based batteries. They also have high energy density, suffer less from the memory effect, and are environmentally friendlier. There are two major types of lithium-based cells: lithium-ion and lithium polymer.

Lithium is the lightest metal and provides the highest energy density of all known metals. Lithium oxidizes very rapidly and is highly flammable and slightly explosive when exposed to air and water. Lithium metal is also corrosive.

Lithium-Ion Battery

Battery cells do not use lithium metal due to safety issues; instead they use lithium compounds. A variety of lithium compounds is used. The term **lithium ion (Li-Ion)** applies to all batteries that use lithium regardless of the materials mixed with the lithium. These compounds have been the focus of much research during the development of lithium-ion batteries. Recently, a manganese lithium-ion battery has been developed that may last twice as long as a NiMH battery.

Li-Ion cells have a high voltage output, 3.6 volts. The compounds used in the cell determine the energy

density of the cell. However, the higher density designs are more dangerous. Safety issues also surface when connecting Li-Ion cells, in series or parallel, to form a battery pack. Not all Li-Ion cells are designed to be used in a battery pack; only cells that meet tight voltage and capacity tolerances should be used. If the connected cells do not have the same output and capacity, the battery pack can be overcharged and cause a fire.

Li-Ion batteries are expensive to produce. This is mostly due to the required protection circuit. Because lithium metal is very reactive and can explode, the cycling of the battery must be monitored. The protection circuit limits the peak voltage of each cell during charging and prevents the voltage from dropping too low during discharge. The temperature of the battery pack is also monitored and charge and discharge activities are controlled to prevent high temperatures. The circuit also contains electronics and/or fuses to prevent polarity reversal.

Chemical Reactions As with most other rechargeable cells, ions move from the anode to the cathode when the cell is providing electrical energy, and during recharging the ions are moved back from the cathode to the anode (**Figure 17-48**). The anode is made of graphite, a carbon compound. The cathode is mostly comprised of graphite and a lithium alloy oxide. The construction of the cathode is one of the areas that researchers are working on to produce a safer and stronger Li-Ion battery.

The electrolyte is also the target of much research. The basic electrolyte is a lithium salt mixed in a liquid. Polyethylene membranes are used to separate the plates inside the cells and, in effect, separate the ions from the electrons. The membranes have extremely small pores that allow the ions to move within the cell.

Charging Li-Ion batteries should be charged with a constant voltage. Charging current should change in response to the voltage of the cell. In other words, as the voltage of the cell increases, the charging current should decrease. Li-Ion batteries should not be fast-charged.

Due to the explosive nature of lithium, certain precautions must be followed when discharging and charging Li-Ion batteries:

- Never connect cells in parallel and/or series that are not designed to be connected together or do not have identical output voltages.
- Never charge or discharge the battery if it is not connected to its protection circuit.

Figure 17-48 The chemical action inside a Li-Ion cell when it is supplying electrical energy and when it is being charged.

- If the protection circuit does not have a temperature sensor, carefully monitor the battery's temperature while charging and discharging.
- Never charge a Li-Ion battery that is physically damaged.

Lithium-Polymer Batteries

The **lithium-polymer (Li-Poly or LiPo) battery** was developed through the continuous research on the Li-Ion battery. The electrolyte used in Li-Poly cells is not a liquid; rather, the lithium salt is held in a solid polymer composite (such as polyacrylonitrile). The polymer electrolyte is not flammable and these batteries are less hazardous than Li-Ion batteries.

The dry polymer electrolyte does not conduct electricity; rather it allows ions to move between the anode and cathode. The polymer electrolyte also serves as the separator between the plates. The dry electrode has very high resistance and therefore cannot provide bursts of current for heavy loads.

Heating the cell to 140°F (60°C) or higher increases its efficiency. The voltage of a Li-Poly cell is about 4.23 volts when fully charged. The cells must be protected to prevent overcharging. However, these cells are more resistant to overcharging than Li-Ion cells and there is much less of a chance for electrolyte leakage.

Li-Poly cells are expensive to manufacturer and have a much higher cost-to-energy ratio than Li-Ion cells. However, because Li-Poly cells do not use a metal case, they are lighter and can be packaged in many ways. As a result of the flexible packaging, Li-Poly cells have a much higher energy density than Li-Ion, NiMH, and NiCad batteries.

In some Li-Poly cells, a gelled electrolyte has been added to enhance ion conductivity. These are called lithium-ion-polymer cells.

ISOLATING HIGH-VOLTAGE SYSTEMS

WARNING!

Careless handling of some hybrid components can lead to serious injury, including death. Always follow and adhere to the precautions given by the manufacturer. These precautions are clearly labeled in their service manuals. Here are just a few of those safety precautions:

- *Make sure the high-voltage system is shut down and isolated from the vehicle before working near or with any high-voltage component.*
- *When working on or near the high-voltage system, even when it is depowered, always use insulated tools.*
- *Never leave tools or loose parts under the hood or close to the battery pack. These can easily cause a short.*
- *Never wear anything metallic, such as rings, necklaces, watches, and earrings, when working on a hybrid vehicle.*
- *Warning and/or caution labels are attached to all high-voltage parts. Be careful not to touch these cables and parts without the correct protective gear, such as lineman's gloves.*
- *Always wear lineman's gloves during the process of depowering and powering the system back up again.*

The procedure for properly depowering and isolating the high-voltage system from the rest of the vehicle is very important and not very difficult. However, each manufacturer has its own procedure that must be followed in the order presented. With the correct information and by following the procedures you can safely work on a hybrid vehicle.

The following discussion covers the depowering procedures for the currently available assist and full hybrids. Other hybrids also have high-voltage systems. These systems should also be depowered before performing any service.

Honda Hybrids

Honda's procedure for depowering the high-voltage systems includes the following steps, which must be followed in the order they appear to avoid serious personal injury and damage to the vehicle's electrical system. Always wear undamaged electrically insulated gloves when inspecting and handling any high-voltage cable or component.

1. Turn the ignition switch off.
2. On many models, the rear seat back must be removed to gain access to the battery module.
3. Remove the switch lid from the IPU cover on the battery module.
4. Then remove the locking cover.
5. Turn the battery module switch off (**Figure 17-49**), and then reinstall the locking cover to secure the switch in the off position.
6. Wait for 5 or more minutes after turning the battery module switch off to allow the ultracapacitors to discharge.
7. Then disconnect the negative cable from the 12-volt battery.
8. Remove the IPU cover.

Figure 17-49 The battery module switch in a Honda hybrid.

9. Locate the terminals for the junction board.
10. Measure the voltage at those terminals. If the voltage is less than 30 volts, the system can be serviced. If the voltage is greater than 30 volts, there is a problem. This must be diagnosed before continuing with any service.
11. When the system is ready to be powered again, make sure all circuits have been securely reconnected, then reverse the depowering sequence.

Toyota Hybrids

All Toyota and Lexus hybrids have the same depowering sequence, although some use a much higher voltage than others. These higher voltage systems require only one additional precaution, that being the wait time for the ultracapacitors to discharge. Toyota calls for a wait of at least 5 minutes. On the vehicles with very high voltages, longer waiting times are safer. The basic procedure for depowering the high-voltage system includes:

1. Remove the key from the ignition switch. If the vehicle has a “smart” key, turn the smart key system off. This may be done by applying pressure to the brake pedal while depressing the start button for at least 2 seconds. If the READY lamp goes off, continue. If it does not, diagnose the problem before continuing.
2. Disconnect the negative (–) terminal cable from the auxiliary 12-volt battery. This should turn the high-voltage system off but does not complete the depowering process.
3. Make sure you are wearing insulated gloves and remove the service plug from the battery module (**Figure 17–50**). To gain access to the plug, you may need to move the carpeting in the rear of the vehicle.
4. Put the service plug in your pocket to prevent others from reinstalling it before the system is ready or while you are working on the vehicle.
5. Put electrical insulating tape over the service plug connector.
6. Wait at least 5 minutes before proceeding or doing any work on or around the high-voltage system.
7. Prior to handling any high-voltage cable or part, check the voltage at the terminals. There should be less than 12 volts.
8. If a high-voltage cable must be disconnected for service, wrap its terminal with insulating tape to prevent a possible short.

Ford Motor Company Hybrids

The hybrids from Ford have a procedure similar to Toyota. However, the service disconnect plug can be

Figure 17-50 Removal of the service plug on a Toyota hybrid to disconnect the high-voltage circuits.

Figure 17-51 To isolate the high-voltage system, turn the service disconnect plug from the LOCK position (1) to the UNLOCK position (2). Then lift it out and reinstall it in the SERVICING/SHIPPING position (3).

installed in different positions, rather than simply be in or out. To isolate the high voltage:

1. Place the gear selector into the park position and remove the ignition key. This should isolate the high-voltage system, but for safety reasons continue through the procedure.
2. Disconnect the negative cable at the 12-volt battery; this should also isolate the high voltage, but continue through this procedure.
3. Lift up the carpeting behind the rear seat.
4. Locate and turn the service disconnect plug from the lock position to the unlock position. Then lift it out. This disconnects the high-voltage battery pack from the vehicle.
5. Reinstall the plug with its arrow at the SERVICING/SHIPPING mark (**Figure 17-51**).

CAUTION!

Although the removal of the plug disconnects the battery pack, it should be returned to its bore but in the servicing/shipping position to prevent debris from entering into the battery pack while services are being performed.

GM's Hybrids

General Motors is currently using different hybrid systems. The most common of these have a 42-volt starter/generator located between the engine and transmission or at the front of the engine connected to the crankshaft via a belt.

Figure 17-52 When the service disconnect switch for a GM hybrid switch is in the horizontal position, the switch is off.

To disconnect the 42-volt system from the vehicle there is a switch on the side of the battery pack called the energy storage box (ESB). The battery pack is located under the rear passenger seat. The service disconnect switch is located behind a removable cover on the battery pack. Once the cover is removed, the switch is turned to its horizontal or off position (**Figure 17-52**). This disconnects the 42-volt system from the rest of the vehicle.

On some vehicles, the generator battery disconnect control module cover should be opened to disconnect the high-voltage system. This cover is a hinged panel attached to the rear of the generator battery carrier assembly. A bolt holds the cover closed and must be removed to open it. The service disconnect switch plunger rests against the generator battery disconnect control module cover. When the cover is opened, the switch will open; it will close when the cover is in a closed position.

General Motors also advises technicians to disconnect the 12-volt battery whenever working under the vehicle's hood and when working on or around any part related to the vehicle's hybrid system.

JUMP-STARTING

When it is necessary to jump-start a car with a discharged battery using a booster battery and jumper cables, follow the instructions shown in **Figure 17-53** to avoid damaging the charging system or creating a hazardous situation. Pay attention to the following precautions:

- Always wear eye protection when making or breaking jumper cable connections.
- Be sure the connections are done correctly and tightly.

Figure 17-53 Proper setup and connections for jump-starting a vehicle with a low battery.

- Make sure all electrical accessories of both vehicles are off.
- When making the connections, do not lean over the battery or accidentally let the jumper cables or clamps touch anything except the correct battery terminals.
- Use only a 12-volt supply as the booster battery.
- The gases around the battery can explode if exposed to flames, sparks, or lit cigarettes.

PROCEDURE

To jump-start a typical hybrid vehicle with the battery of another vehicle, follow this procedure:

1. Park the booster vehicle close to the hood of the disabled vehicle, making sure that the two vehicles do not touch.
2. Set the parking brake on both vehicles.
3. Remove the ignition key and turn off accessories on both vehicles.
4. Open the hoods or trunks to gain access to the batteries. On some vehicles, there is a special jump-starting terminal under the hood.
5. Connect the clamp of the positive (red) jumper cable to the positive terminal on the weak battery.
6. Connect the clamp at the other end of the positive (red) jumper cable to the positive (+) terminal on the booster battery.
7. Connect the clamp of the negative (black) jumper cable to the negative (–) terminal on the booster battery.
8. Connect the clamp at the other end of the negative (black) jumper cable to an exposed metal part of the dead vehicle's engine, away from the battery and the fuel injection system. Never use a fuel line, engine camshaft or rocker arm covers, or the intake manifold for making this connection.
9. Make sure the jumper cables are clear of fan blades, belts, moving parts of both engines, or any fuel delivery system parts.

10. Run the engine of the booster vehicle at a medium speed for about 5 minutes.
11. Now attempt to start the disabled vehicle.
12. If the vehicle does not start, check the connections of the jumper cables and if a problem is found, correct it and try again. If the engine still does not start, the battery should be replaced.
13. Once the disabled vehicle has started, allow both engines to run for about 5 minutes.
14. Disconnect the negative cable from the disabled vehicle and then from the booster battery.
15. Next, disconnect the positive cable from the disabled vehicle and then from the booster battery.

High-Voltage Batteries

If the starting or high-voltage battery in a hybrid vehicle is discharged, the engine will not start nor will the vehicle be able to operate on electric power only. If the engine cranks but does not start, the high-voltage battery may need to be jumped. Manufacturers have built-in ways to jump-start these vehicles, if and when the batteries go dead. Some hybrid vehicles have separate procedures for jump-starting—one for the low-voltage battery and the other for the high-voltage battery. The basic connection from a booster battery to the dead battery is made in the same way as a conventional vehicle. However, the connecting points may be different and there are certain precautions to consider when jump-starting. Also refer to the service information prior to jump-starting a hybrid.

To jump-start, or get the engine running, on a Ford Escape or Mariner hybrid, make sure the ignition is *off* before proceeding. Then open the access panel on the driver's side foot well and press the jump-start button (Figure 17-54). Wait at least 8 minutes before

Figure 17-54 To jump-start a Ford Escape or Mariner hybrid high-voltage battery, turn the ignition *off*, open the access panel on the driver's side foot well, and press the jump-start button.

continuing. This is important! If you continue sooner, the energy from the auxiliary battery will not be able to supply enough power to start the engine with the battery pack. When you depress the button, the system sends energy from the auxiliary battery to the battery pack. If the auxiliary battery has ample energy, it will be enough to start the engine. After the wait time, the warning lamp may blink for up to 2 minutes. After it stops, attempt to start the engine. If the engine still does not start, try again in a couple of minutes. If the engine still does not start, the low-voltage battery must be recharged or the vehicle jump-started through the 12-volt battery.

CASE STUDY I

A customer complains that the vehicle will not start without having to jump the battery. The technician learns that this happens every time the customer attempts to start the vehicle. The customer also says the voltmeter in the dash has been reading higher than normal.

The technician verifies the complaint. The engine turns over very slowly for a few seconds, then does not turn. After jumping the battery to get the vehicle into the shop, the technician makes a visual inspection of the battery and cables. The open circuit voltage test shows a voltage of 12.5 volts across the terminals. When a load test is conducted, the voltage drops to 7.8 volts at 80°F (26.7°C). After 10 minutes, the open circuit voltage is back up to 12.5 volts. The technician determines that the battery is sulfated and calls the customer with an estimate of repair costs. The customer agrees to have the battery replaced, which cures the problem.

CASE STUDY II

A very low mileage late-model Buick had been sitting in a garage for about 2 months. The owner no longer drove but went out every day or so and ran the engine for a while. He eventually sold the car and the day

the new owner came to drive it away, the battery was totally dead. After a few wrong assumptions made as to why the battery was dead, a service truck was called in to jump the battery.

While connecting the booster battery to the vehicle, heavy sparking took place as the negative cable was connected. This was ignored and the owner started the car. It ran well but the new owner was concerned there was a problem and decided not to attempt to drive it home until he had someone follow him. That could happen in a few days. During this period, the owner went out daily to start and run the engine. For 3 days it started, but on the fourth day the battery was dead again. The owner contacted the new owner, who suggested that the vehicle be jumped and driven to a shop. Once at the shop, the technician tried to drive the car inside. The battery was dead. Again it was jumped and driven in for testing.

Battery tests were conducted and no problems identified. The technician called the new owner and reported the results with a suggestion that the battery probably just needed a slow charge. This was done and the owner had the car delivered back to him. The next day, he went to start the car and again the battery was dead. The shop was called and had the vehicle towed in. And again the battery needed to be jumped. This time, however, someone paid attention to the sparks when the jumper cables were connected. Once the car was in the shop, the battery was retested and was found to have low open circuit voltage. The technician then wiggled the battery and retested it. This time it had normal voltage. This confirmed the cause of the problem. It also explained why there was heavy sparking when it was connected to the booster battery. The battery had a loose plate and it was shorting out a battery cell sometimes. A new battery was installed and the new owner is still driving the hardly ever used Buick with a new battery.

KEY TERMS

Absorbed glass mat (AGM) battery	Load test
Ampere-hour (AH) rating	Maintenance-free battery
Battery Council International (BCI)	Nickel-cadmium (NiCad)
Capacitance test	Nickel-metal hydride (NiMH)
Capacity test	Open circuit voltage
Cold cranking amps (CCA)	Parasitic load
Conductance test	Plates
Cranking amps (CA) rating	Plate strap
Cylindrical cell	Prismatic cells
Electrochemical reaction	Recombinant battery
Electrodes	Reserve capacity (RC) rating
Element	Separator
Fast charging	Slow charge
Grid	Specific gravity
Hybrid battery	Sponge lead (Pb)
Lead peroxide (PbO ₂)	Sulfation
Lithium-ion (Li-Ion)	Trickle charge
Lithium-polymer (Li-Poly or LiPo) battery	Valve-regulated lead-acid (VRLA) batteries
	Watt-hour rating

SUMMARY

- The primary source for electrical power in all automobiles is the battery.
- Batteries are devices that convert chemical energy into electrical energy through electrochemical reactions.
- Batteries are normally made up of electrochemical cells connected together. Each cell has three major parts: an anode (negative plate or electrode), a cathode (positive plate or electrode), and electrolyte.
- Open circuit voltage is the voltage measured across the battery when there is no load on the battery.
- Operating voltage is the voltage measured across the battery when it is under a load.
- The ampere-hour (AH) rating is the amount of steady current that a fully charged battery can supply for 20 hours at 80°F (26.7°) without the cell's voltage dropping below a predetermined level.
- A battery's watt-hour rating is determined at 0°F (−17.7°C) and is calculated by multiplying a battery's amp-hour rating by the battery's voltage.
- The cold cranking amps (CCA) rating is determined by the load, in amperes, that a battery is able to deliver for 30 seconds at 0°F (−17.7°C) without its voltage dropping below a predetermined level.
- The cranking amps (CA) rating is a measure of the current a battery can deliver at 32°F (0°C) for 30 seconds and maintain voltage at a predetermined level.
- The reserve capacity (RC) rating is determined by the length of time, in minutes, that a fully charged starting battery at 80°F (26.7°) can be discharged at 25 amperes before battery voltage drops below 10.5 volts.
- There are many different types and designs of batteries available; the primary difference is the chemicals used in the cells, such as lead-acid, nickel-cadmium (NiCad), nickel-metal hydride (NiMH), sodium-sulfur (NaS), sodium-nickel-chloride, lithium-ion (Li-Ion), lithium-polymer (Li-Poly), and nickel-zinc.
- High-voltage battery packs are assemblies of cylindrical or prismatic cells.
- The most common automotive batteries are lead-acid designs. The wet cell, gel cell, absorbed glass mat (AGM), and valve regulated are versions of the lead-acid battery.
- A lead-acid battery consists of grids, positive plates, negative plates, separators, elements, electrolyte, a container, cell covers, vent plugs, and cell containers. Maintenance-free batteries have no holes or caps, but they do have gas vents. Sealed maintenance-free batteries do not require the gas vents used on other maintenance-free designs.
- Improper electrolyte levels, temperature, corrosion, overcharging, undercharging/sulfation, poor mounting, and cycling affect the service life of a battery.
- Depending on the design of the battery, its condition, SOC, and capacity can be measured by different tests: battery leakage test, specific gravity tests, built-in hydrometers, open circuit voltage test, capacity test, and capacitance or conductance test.
- Parasitic loads are current drains that exist when the key is off and may be normal or caused by a problem.
- To charge a battery, a given charging current is passed through the battery for a period of time. Fast chargers are more popular, but slow charging is the only safe way to charge a sulfated battery.
- Nickel-metal hydride (NiMH) cells are available in the cylindrical and prismatic designs and both are used in hybrid vehicles.

- Lithium-based batteries are similar in construction to nickel-based batteries but have higher energy density, suffer less from the memory effect, and are environmentally friendlier.
- There are two major types of lithium-based cells: lithium-ion and lithium-polymer.
- Always follow the correct procedure when jump-starting a vehicle.
- Some hybrid vehicles have separate procedures for jump-starting: one for the low-voltage battery and the other for the high-voltage battery.

REVIEW QUESTIONS

- What is a parasitic load?
- What design characteristics determine the current capacity of a battery?
- How is a battery leakage test conducted?
- Describe the difference between cylindrical and prismatic battery cells.
- How can you identify the high-voltage system in most hybrid vehicles?
- How many volts are present in a fully charged 12-volt battery?
- What is meant by the term *specific gravity*?
- What causes gassing in a battery?
- List five things that shorten the life of a battery.
- True or False?* All electrochemical batteries have three major parts: an anode, a cathode, and an electrolyte.
- True or False?* A fully charged new battery will have a low conductance reading.
- True or False?* Batteries are recycled more than any other item.
- True or False?* Heating a lithium-polymer cell increases its efficiency.
- Which of the following statements about NiMH cells is true?
 - The cylindrical design requires less storage space but has less energy density than the prismatic design.
 - They have a relatively long service life.
 - Service life can be extended by frequent deep cycles.
 - They do not respond well to overcharging; they should be trickle charged.
- Which of the following statements about battery ratings is true?
 - The ampere-hour rating is defined as the amount of steady current that a fully charged battery can supply for 1 hour at 80°F (26.7°C) without the cell voltage falling below a predetermined voltage.
 - The cold cranking amps rating represents the number of amps that a fully charged battery can deliver at 0°F (−17.7°C) for 30 seconds while maintaining a voltage above 9.6 volts for a 12 V battery.
 - The cranking amp rating expresses the number of amperes a battery can deliver at 32°F (0°C) for 30 seconds and maintain at least 1.2 volts per cell.
 - The reserve capacity rating expresses the number of amperes a fully charged battery at 80°F can supply before the battery's voltage falls below 10.5 volts.

ASE-STYLE REVIEW QUESTIONS

- Technician A uses a voltmeter to test the open circuit voltage of a battery. Technician B uses the results of an open circuit voltage test to determine the battery's state of charge. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- Technician A says that the reserve rating of a battery is the amount of steady current that a fully charged battery can supply for 20 hours without the voltage falling below 10.5 volts. Technician B says that ampere-hour ratings state how many hours the battery is capable of supplying 25 amperes. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B
- Technician A says that battery straps should be used whenever a battery is lifted. Technician B says that when a battery is removed, the positive cable should be disconnected first. Who is correct?
 - Technician A
 - Technician B
 - Both A and B
 - Neither A nor B

4. Technician A says that larger batteries have higher current capacities. Technician B says that BCI group numbers identify the features of a battery. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
5. Technician A says that battery corrosion is commonly caused by spilled electrolyte. Technician B says that battery corrosion is commonly caused by electrolyte condensation from gassing. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
6. Technician A says that before a battery is removed, a memory saver ought to be installed. Technician B says that before a battery is removed, the positive cable should be disconnected and the area around the battery should be cleaned. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
7. Technician A says that nickel-metal hydride batteries have a negative plate that contains nickel hydroxide. Technician B says that the alkaline electrolyte has no active role in the chemical reaction. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
8. While working with an NiMH battery: Technician A says that if the battery is exposed to extreme cold, it is possible that hydrogen will be released from the battery and hydrogen can be explosive when introduced to flame or sparks. Technician B says that the cells contain an electrolyte comprised mostly of sulfuric acid. Exposure to the electrolyte can cause skin/eye irritation and/or burns. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
9. Technician A always wears safety glasses or goggles when working with batteries. Technician B says that there is no need to seek medical help if electrolyte gets in your eyes as long as you flush your eyes immediately after the electrolyte hits them. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
10. While discussing the results of a load test: Technician A says that if a battery fails a load test but the voltage rises above 12.4 volts when the load is removed, the battery should be replaced. Technician B says that if a battery fails a load test but the voltage rises above 12.4 volts when the load is removed, the battery is able to hold a charge. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B

STARTING AND TRACTION MOTOR SYSTEMS

OBJECTIVES

- Describe the basic operation of all electric motors. ■ Identify the major parts of a DC motor.
- Explain the purpose of the starting system. ■ Describe the purpose and major components of the starting and starter control circuits. ■ Describe the different types of magnetic switches and starter drives. ■ Describe the different types of starting motors used in today's vehicles. ■ Inspect and test starter relays and solenoids and the switches, connectors, and wires of starter control circuits.
- Perform starter circuit voltage drop tests and the starter current draw test. ■ Disassemble, clean, inspect, test, repair, and reassemble a starting motor. ■ Explain the basic operation of an AC motor.
- Understand the characteristics of three-phase AC voltage and describe the operation of a three-phase AC motor. ■ Explain the purposes of a controller in a motor circuit.

Electric motors are used to start the engine and, in hybrid and fuel cell vehicles, to move the vehicle. They also are used to operate many different accessories. For the most part, the basic difference between the motors used in these applications is the size and power output. Most of these motors are powered by DC voltage and are part of relatively simple circuits. Traction or drive motors use AC voltage and are controlled by rather complex circuits. Regardless of the voltage used to power the motor, the operation of all electric motors is based on the basic principles of magnetism.

BASICS OF ELECTROMAGNETISM

Electricity and magnetism are related. One can be used to create the other. Current flowing through a wire creates a magnetic field around the wire. Moving a wire through a magnetic field creates current flow in the wire.

Magnetism

A substance is said to be a magnet if it has the property of magnetism—the ability to attract such substances as iron, steel, nickel, or cobalt. A magnet has two points of maximum attraction, one at each end of the magnet. These points are designated the north

pole and the south pole (**Figure 18–1A**). When two magnets are brought together, opposite poles attract (**Figure 18–1B**), while similar poles repel each other (**Figure 18–1C**).

A magnetic field, called a **flux field**, exists around every magnet. The field consists of imaginary lines along which the magnetic force acts. These lines emerge from the north pole and enter the south pole, returning to the north pole through the magnet itself. All lines of force leave the magnet at right angles to the magnet. None of the lines cross each other and all are complete.

Electromagnets

Magnets can occur naturally in the form of a mineral called magnetite. Artificial magnets can be made by inserting a bar of magnetic material inside a coil of insulated wire and passing current through the coil. Another way of creating a magnet is by stroking the magnetic material with a bar magnet. Both methods force the randomly arranged molecules of the magnetic material to align themselves along north and south poles.

Artificial magnets can be either temporary or permanent. Temporary magnets are usually made of soft iron. They are easy to magnetize but quickly lose their

Figure 18-1 (A) In a magnet, lines of force emerge from the north pole and travel to the south pole before passing through the magnet back to the north pole. (B) Unlike poles attract, while (C) similar poles repel each other.

magnetism when the magnetizing force is removed. Permanent magnets are difficult to magnetize. However, once magnetized they retain this property for very long periods.

The earth is a very large magnet, having a North Pole and a South Pole, with lines of magnetic force running between them. This is why a compass always aligns itself to straight north and south.

In 1820, a simple experiment discovered the existence of a magnetic field around a current-carrying wire. When a compass was held over the wire, its needle aligned itself at right angles to the wire (**Figure 18-2**). The lines of magnetic force are concentric circles around the wire. The density of these circular lines of force is very heavy near the wire and decreases farther away from the wire. As is also shown in the same figure, the polarity of a current-carrying wire's magnetic field changes depending on the direction the current is flowing through the wire. These magnetic lines of force or flux lines do not move or flow around the wire. They simply have a direction as shown by their effect on a compass needle.

Figure 18-2 When current is passed through a conductor such as a wire, magnetic lines of force are generated around the wire at right angles to the direction of the current flow.

MAGNETIC FIELDS ADD TOGETHER.

Figure 18-3 Increasing the number of conductors carrying current in the same direction increases the strength of the magnetic field around them.

Flux Density The more flux lines, the stronger the magnetic field at that point. Increasing current will increase **flux density**. Also, two conducting wires lying side by side carrying equal currents in the same direction create a magnetic field equal in strength to one conductor carrying twice the current. Therefore, adding more wires increases the magnetic field (**Figure 18-3**).

Coils Looping a wire into a coil concentrates the lines of flux inside the coil. The resulting magnetic field is the sum of the single-loop magnetic fields (**Figure 18-4**). The overall effect is the same as placing many wires side by side, each carrying current in the same direction.

Figure 18-4 (A) Forming a wire loop concentrates the lines of force inside the loop. (B) The magnetic field of a wire coil is the sum of all the single-loop magnetic fields.

Magnetic Circuits and Reluctance

Just as current can only flow through a complete circuit, the lines of flux created by a magnet can only occupy a closed magnetic circuit. The resistance that a material offers to the passage of magnetic flux lines is called **reluctance**. Magnetic reluctance can be compared to electrical resistance.

Reconsider the coil of wire shown in Figure 18-4. The air inside the coil has very high reluctance and limits the magnetic strength produced. However, if an iron core is placed inside the coil, magnetic strength increases tremendously. This is because the iron core has a very low reluctance (**Figure 18-5**).

When a coil of current-carrying wire is wound around an iron core, it becomes a usable electromagnet. The strength of an electromagnet's magnetic field is directly proportional to the number of turns of wire and the current flowing through them.

The equation for an electromagnetic circuit is similar to Ohm's law for electrical circuits. It states that the number of magnetic lines is proportional to the ampere-turns divided by the reluctance. To summarize:

- The magnetic polarity of the coil depends on the direction of current flow through the loop.
- Field strength increases if current through the coil increases.
- Field strength increases if the number of coil turns increases.
- If reluctance increases, field strength decreases.

Figure 18-5 Placing a soft iron core inside a coil greatly reduces the reluctance of the coil and creates a usable electromagnet.

Motors

An electric motor converts electric energy into mechanical energy. Through the years, electric motors have changed substantially in design; however, the basic operational principles have remained the same. That principle is easily observed by taking two bar magnets and placing them end to end with each other. If the ends have the same polarity, they will push away from each other. If the ends have the opposite polarity, they will move toward each other and form one magnet.

If we put a pivot through the center of one of the magnets to allow it to spin and moved the other magnet toward it, the first magnet will either rotate away from the second or move toward it (**Figure 18-6**). This is basically how a motor works. Although we do not observe a complete rotation, we do see part of one, perhaps a half turn. If we could change the polarity of the second magnet, we would get another half turn. So in order to keep the first magnet spinning, we need to change the polarity immediately after it moves halfway. If we continued to do this, we would have a motor.

In a real motor, an electromagnet is fitted on a shaft. The shaft is supported by bearings or bushings to allow it to spin and to keep it in the center of the motor. Surrounding, but not touching, this inner magnet is a stationary permanent magnet or an electromagnet. Actually, there is more than one magnet or magnetic field in both components. The polarity of these magnetic fields is quickly switched and we have a constant opposition and attraction of magnetic fields. Therefore, we have a constantly rotating inner magnetic field, the shaft of which can do work due to the forces causing it to rotate. The torque of a motor varies with rotational speed, motor design, and the amount of current draw the motor has. The rotational

Figure 18-6 (A) Like poles repel. (B) Unlike poles are attracted to each other. Then if we change the polarity of the coils, (C) the like poles again repel.

Figure 18-7 A simple electric motor.

speed depends on the motor's current draw, the design of the motor, and the load on the motor's rotating shaft.

The basic components of a motor are the stator or field windings, which are the stationary parts of the motor, and the rotor or armature, which is the rotating part (Figure 18-7). The field windings are comprised of slotted cores made of thin sections of soft iron wound with insulated copper wire to form one or more pairs of magnetic poles. Some motors have the field windings wound around iron anchors, called pole shoes. The armature is comprised of loops of current-carrying wire. The loops are formed around a metal with low reluctance to increase the magnetic field. The magnetic fields around the armature are pushed away by the magnetic field of the field windings, causing the armature to rotate away from the windings' fields.

The field windings or the armature may be made with permanent magnets rather than electromagnets. Both cannot be permanent magnets. An electromagnet allows for a change in the polarity of the magnetic fields, which keeps the armature spinning. Changing the direction of current flow changes the magnetic polarities.

STARTING MOTORS

The starting motor (Figure 18-8) is a special type of electric motor designed to operate under great electrical loads and to produce great amounts of torque for short periods.

All starting motors are generally the same in design and operation. Basically the starter motor consists of a housing, field coils (windings), an armature, a commutator with brushes, and end frames (Figure 18-9).

Figure 18-8 A cutaway of a starter motor. Courtesy of Robert Bosch GmbH, www.bosch-presse.de

The **starter housing** or **starter frame** encloses the internal parts and protects them from damage, moisture, and foreign materials. The housing also supports the field coils.

The **field coils** and their **pole shoes** (Figure 18-10) are securely attached to the inside of the housing. The field coils are insulated from the housing but are connected to a terminal that protrudes through the outer surface of the housing.

The field coils and pole shoes are designed to produce strong stationary electromagnetic fields within the starter when current flows to it. The magnetic fields are concentrated at the pole shoe. The coils are wound around respective pole shoes in opposite directions to create opposing magnetic fields.

The field coils connect in series with the armature winding through the starter **brushes**. This permits all current passing through the field coil circuit to also pass through the armature windings.

The **armature** is the rotating part of a starter. It is located between the starter drive and commutator end frames and the field windings. Current passing through the armature produces a magnetic field in each of its conductors. The reaction between the armature's magnetic field and the magnetic fields produced by the field coils causes the armature to rotate (Figure 18-11). This is the mechanical energy that is then used to crank the engine.

The armature has two main components: the armature windings and the **commutator**. Both mount to the armature shaft (Figure 18-12). The armature windings are made of heavy flat copper strips or wires that form a single loop and can handle the heavy current flow. The sides of these loops fit into slots in the armature core or shaft, but they are insulated from it.

The coils connect to each other and to the commutator so that current from the field coils flows

Figure 18-9 A typical starter motor assembly. Courtesy of Toyota Motor Sales, U.S.A., Inc.

Figure 18-10 Example of a field coil and pole shoe.

Figure 18-11 Rotation of the conductor is in the direction of the weaker magnetic field.

through all of the windings at the same time. This action generates a magnetic field around each armature winding, resulting in a repulsion force all around the conductor. This repulsion force causes the armature to turn.

Figure 18-12 The armature of a starter motor.

The commutator assembly is made up of heavy copper segments separated from each other and the armature shaft by insulation. The commutator segments connect to the ends of the armature windings.

Starter motors have two to six brushes that ride on the commutator segments and carry the heavy current from the stationary field coils to the rotating armature windings. Each end of the armature windings is connected to one segment of the commutator. Carbon brushes are connected to one terminal of the power supply. The brushes contact the commutator segments conducting current to and from the armature coils.

The brushes mount on and operate in some type of holder, which may be a pivoting arm design inside the starter housing or frame (**Figure 18-13**). However, in many starters the brush holders are secured to the starter's end frame. Springs hold the brushes

Figure 18-13 The location of the starter motor brushes and commutator.

against the commutator with the correct pressure. Finally, alternate brush holders are insulated from the housing or end frame. Those between the insulated holders are grounded.

The **end frame** is a metal plate that bolts to the commutator end of the starter housing. It supports the commutator end of the armature with a bushing or bearing.

Operating Principles

The starter motor converts current into torque through the interaction of magnetic fields. The magnetic field developed at the field windings and the armature have opposite polarities. When the armature windings are placed inside the field windings, part of the armature coil is pushed in one direction as the field opposes the field in the windings. This causes the armature to begin to rotate. As the armature moves, the contact between a brush and commutator segment is broken and the brush contacts a new segment. This causes a reverse in the polarity of the magnetic field around the armature. The new opposition of magnetic fields causes the armature to rotate more. This process continues and the armature continues to rotate until current stops flowing to the armature.

Many armature segments are used. This provides for a uniform turning motion because as one segment rotates past a brush, another immediately takes its place. This also provides for constant torque.

The number of coils and brushes may differ among starter motor models. The armature may be wired in series with the field coils (**series motor**); the field coils may be wired parallel or shunted across

the armature (**shunt motors**); or a combination of series and shunt wiring (**compound motors**) may be used (**Figure 18-14**).

A series motor develops its maximum torque at startup and develops less torque as speed increases. It is ideal for applications involving heavy starting loads.

Shunt or parallel-wound motors develop considerably less startup torque but maintain a constant speed at all operating loads. Compound motors combine the characteristics of good starting torque with constant speed. This design is particularly useful for applications in which heavy loads are suddenly applied. In a starter motor, a shunt coil is frequently used to limit the maximum free speed at which the starter can operate.

Figure 18-14 Starter motors are grouped according to how they are wired: (A) in series, (B) in parallel (shunt), or (C) a compound motor using both series and shunt coils.

Figure 18-15 Permanent magnet-type starter assembly.

Permanent Magnet Motors A recent change in starter and accessory motors is the use of permanent magnets instead of electromagnets as field coils. Electrically, this type of motor is simpler. It does not require current for field coils. Current is delivered directly to the armature through the commutator and brushes (**Figure 18-15**). With the exception of no electromagnets in the fields, this functions exactly as the other motors. Maintenance and testing procedures are the same as for other designs. Notice the use of a planetary gear reduction assembly on the front of the armature. This allows the armature to spin with increased torque, resulting in improved starter cold-cranking performance.

!

WARNING!

Permanent magnet motors require special handling because the permanent magnet material is quite brittle and can be destroyed with a sharp blow or if the motor is dropped.

Counter EMF The amount of torque from a starting motor depends on a number of things. One of the most important is current draw. The slower the motor turns, the more current it will draw. This is why a starter motor will draw large amounts of current when the engine is difficult to crank. A motor needs more torque to crank a difficult-to-start engine. The relationship between current draw and motor

Figure 18-16 A magnetic field forms around a current-carrying conductor according to the direction of current flow. When a wire is formed into a coil, there are repelling poles that result in CEMF.

speed is explained by the principles of **counter EMF (CEMF)**. Electromotive force (EMF) is another name for voltage.

When the armature rotates within the field windings, conditions exist to induce a voltage in the armature. Voltage is induced anytime a wire is passed through a magnetic field. When the armature, which is a structure with many loops of wire, rotates past the field windings, a small amount of voltage is induced (**Figure 18-16**). This voltage opposes the voltage supplied by the battery to energize the armature. As a result, less current is able to flow through the armature.

The faster the armature spins, the more induced voltage is present in the armature. The more voltage induced in the armature, the more opposition there is to normal current flow to the armature. The induced voltage in the armature opposes or is counter to the battery's voltage. This is why the induced voltage is called CEMF.

The effects of CEMF are quite predictable. When the armature of the motor turns slowly, low amounts of voltage are induced and, therefore, low amounts of CEMF are present. The low CEMF permits higher current flow. In fact, the only time a starter motor draws its maximum amount of current is when the armature is not rotating.

STARTING SYSTEM

The starting system is designed to turn or crank the engine until it can operate under its own power. To do this, the starter motor is engaged to the engine's flywheel. As it spins, it turns the engine's crankshaft. The sole purpose of the starting system is to crank the engine fast enough to run. The engine's ignition and fuel system provide the spark and fuel for engine operation, but they are not considered part of the starting system. They do affect how well an engine starts.

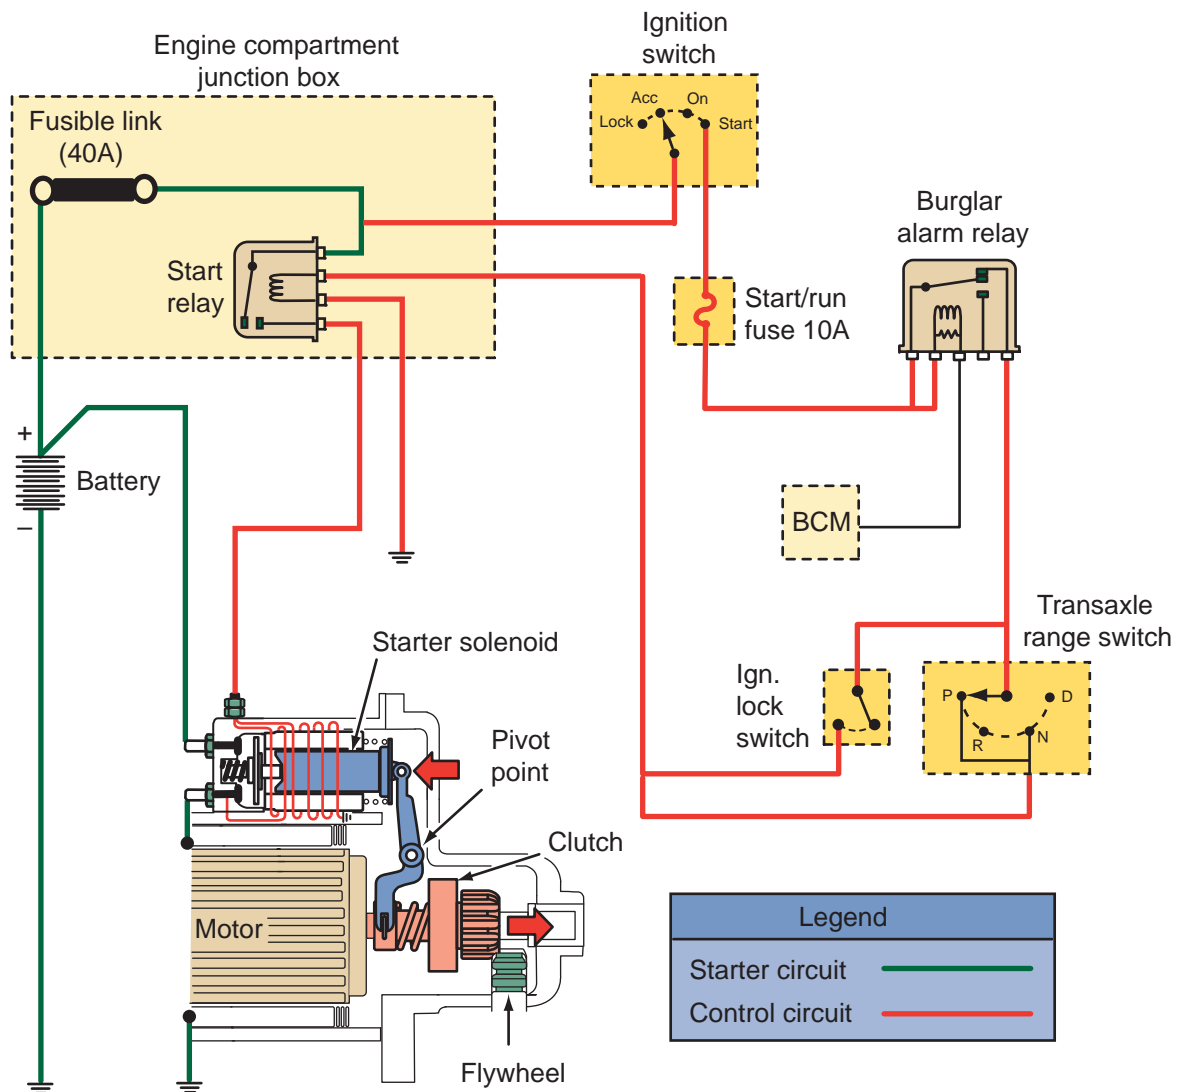

Figure 18-17 The starting system is made up of two separate systems: the starter and control systems.

SHOP TALK

A diesel engine does not have an ignition system. These engines run on the heat of compression. When they are cold and are being started, glow plugs are energized to heat the air-fuel mixture in the cylinders. Glow plugs are simple heaters and do not function as a spark plug. Once the engine is running and warmed up, the glow plug circuit is shut down. If the glow plug circuit is not operating properly, the engine may have a difficult time starting or it may not start at all.

A typical starting system has six basic components and two distinct electrical circuits. The components are the battery, ignition switch, battery cables, magnetic switch (either an electrical relay or a solenoid), starter motor, and the starter safety switch.

The starter motor draws a great deal of current from the battery. A large starter motor might require

250 or more amperes of current. This current flows through the large cables that connect the battery to the starter and ground.

The driver controls the flow of this current using the ignition switch normally mounted on the steering column. The battery cables are not connected to the switch. Rather, the system has two separate circuits: the starter circuit and the control circuit (**Figure 18-17**). The starter circuit carries the heavy current from the battery to the starter motor through a magnetic switch in a relay or solenoid. The control circuit connects battery power at the ignition switch to the magnetic switch, which controls the high current to the starter motor.

STARTER CIRCUIT

The starter circuit carries the high current flow within the system and supplies power for the actual engine cranking. Components of the starter circuit are the battery, battery cables, magnetic switch or solenoid, and the starter motor.

Battery and Cables

Many of the problems associated with the starting system can be solved by troubleshooting the battery and its related components.

The starting circuit requires two or more heavy-gauge cables. One of these cables connects between the battery's negative terminal and the engine block or transmission case. The other cable connects the battery's positive terminal with the solenoid. On vehicles equipped with a **starter relay**, two positive cables are needed. One runs from the positive battery terminal to the relay and the second from the relay to the starter motor terminal. In any case, these cables carry the required heavy current from the battery to the starter and from the starter back to the battery.

Cables must be heavy enough to comfortably carry the required current load. Cranking problems can be created when undersized cables are installed. With undersized cables, the starter motor does not develop its greatest turning effort and even a fully charged battery might be unable to start the engine.

Magnetic Switches

Every starting system contains some type of magnetic switch that enables the control circuit to open and close the starter circuit. This magnetic switch can be one of several designs.

Solenoid The solenoid-actuated starter is by far the most common starter system used. A solenoid is an electromechanical device that uses the movement of a plunger to exert a pulling or holding force. As shown in **Figure 18-18**, the solenoid mounts directly on top of the starter motor.

Figure 18-18 Example of a solenoid-actuated starter where the solenoid mounts directly to the starter motor.

In this type of starting system, the solenoid uses the electromagnetic field generated by its coil to perform two distinct jobs.

The first is to push the drive pinion of the starter motor into mesh with the engine's flywheel. This is the solenoid's mechanical function. The second job is to act as an electrical relay switch to energize the motor once the drive pinion is engaged. Once the contact points of the solenoid are closed, full battery current flows to the starter motor.

The solenoid assembly has two separate windings: a **pull-in winding** and a **hold-in winding**. The two windings have approximately the same number of turns but are wound from different size wire. Together these windings produce the electromagnetic force needed to pull the plunger into the solenoid coil. The heavier pull-in windings draw the plunger into the solenoid, while the lighter-gauge windings produce enough magnetic force to hold the plunger in this position.

Both windings are energized when the ignition switch is turned to the start position. When the plunger disc makes contact with this solenoid terminal, the pull-in winding is deactivated. At the same time, the plunger contact disc makes the motor feed connection between the battery and the starting motor, directing current to the field coils and starter motor armature for cranking power.

As the solenoid plunger moves, the shift fork also pivots on the pivot pin and pushes the starter drive pinion into mesh with the flywheel ring gear. When the starter motor receives current, its armature starts to turn. This motion is transferred through an overrunning clutch and pinion gear to the engine flywheel and the engine is cranked.

With this type of solenoid-actuated direct drive starting system, teeth on the **pinion gear** may not immediately mesh with the flywheel ring gear. If this occurs, a spring located behind the pinion compresses so the solenoid plunger can complete its stroke. When the starter motor armature begins to turn, the pinion teeth quickly line up with the flywheel teeth and the spring pressure forces them to mesh.

Starter Relay Starter relays (**Figure 18-19**) are similar to starter solenoids. However, they are not used to move the drive pinion into mesh. They are used as an electrical relay or switch. When current from the ignition switch arrives at the relay, a strong magnetic field is generated in the relay's coil. This magnetic force pulls the plunger contact disc up against the battery terminal and the starter terminal of the relay, allowing full current flow to the starter motor.

Figure 18-19 A starter relay/solenoid mounted on a vehicle.

A secondary function of the starter relay is to provide an alternate electrical path to the ignition coil during cranking. This current flow bypasses the resistance wire (or ballast resistor) in the ignition primary circuit. This is done when the plunger disc contacts the ignition by-pass terminal on the relay. Not all systems have an ignition by-pass setup.

All positive engagement starters use a relay in series with the battery cables to deliver current through the shortest possible battery cables. Some vehicles use both a starter relay and a starter motor-mounted solenoid. The relay controls current flow to the solenoid, which in turn controls current flow to the starter motor. This reduces the amount of current flowing through the ignition switch. In other words, it takes less current to activate the relay than to activate the solenoid.

Positive Engagement Movable Pole Shoe Drive
Positive engagement movable pole shoe drive starters (**Figure 18-20**) are found mostly on older Ford products. In this design, the drive mechanism is an integral part of the motor, and the drive pinion is engaged with the flywheel before the motor is energized.

When the ignition switch is moved to the start position, the starter relay closes, and full battery current is delivered to the starter. This current runs through the winding of the movable pole shoe and through a set of contacts to ground. This generates a magnetic force that pulls down the movable pole shoe. It also forces the drive pinion to engage the flywheel ring gear using a lever action and opens the contacts. A small holding coil keeps the movable shoe

Figure 18-20 A positive engagement starter.

and lever assembly engaged during cranking. When the engine starts, an overrunning clutch prevents the flywheel from spinning the armature.

When the ignition switch is released from the start position, both the pole shoe and lever return to their original positions.

Starter Drives

The starter drive is the device that couples the armature with the flywheel. A pinion gear at one end of the armature meshes with the teeth on the outside of the flywheel (**Figure 18-21**). The spinning armature then turns the flywheel. To prevent damage to the pinion gear or the ring gear on the flywheel, the pinion must mesh with the ring gear before the armature begins to spin. To help ensure smooth engagement, the end of the pinion gear is tapered (**Figure 18-22**). To disengage the pinion from the flywheel, the pinion is mounted to the armature via an overrunning clutch.

Figure 18-21 Starter drive pinion gear is used to turn the engine's flywheel.

Figure 18-22 The pinion gear teeth are tapered to allow for smooth engagement.

Overrunning Clutch Once the engine starts, its speed increases. If the starter motor remains connected to the engine through the flywheel, it will spin at very high speeds, destroying the armature and other parts.

To prevent this, the starter drive must be disengaged as soon as the engine turns faster than the starter. In most cases, the pinion remains engaged until current stops flowing to the starter. To prevent the armature from spinning at engine speed, an overrunning clutch is used.

The clutch housing is internally splined to the armature shaft. The drive pinion turns freely on the armature shaft within the clutch housing. When the clutch housing is driven by the armature, the spring-loaded rollers are forced into the small ends of their tapered slots and wedged tightly against the pinion barrel. This locks the pinion and clutch housing solidly together, permitting the pinion to turn the flywheel and, thus, crank the engine.

When the engine starts (**Figure 18-23**), the flywheel spins the pinion faster than the armature. This releases the rollers, unlocking the pinion gear from the armature shaft. The pinion then freely spins on the armature shaft. Once current flow is stopped, the pinion is then pulled away from the flywheel. The overrunning clutch is moved in and out of mesh by the starter drive linkage.

Gear Reduction Drive The armature of some starter motors does not directly drive the starter drive gear. Rather it drives a small gear that is permanently meshed with a larger gear (**Figure 18-24**). This provides for a gear reduction and allows a small, high-speed motor to provide high torque at a satisfactory cranking speed. This starter design also tends to require lower current during engine startup. Some starters use a planetary gearset for gear reduction.

Figure 18-23 When the engine starts, the flywheel spins the pinion gear faster, which releases the rollers from the wedge.

Figure 18-24 A gear reduction-drive starter.

CONTROL CIRCUIT

The control circuit allows the driver to use a small amount of battery current to control the flow of a large amount of current in the starting circuit.

The entire circuit usually consists of an ignition switch connected through normal-gauge wire to the battery and the magnetic switch (solenoid or relay). When the ignition switch is turned to the start position, a small amount of current flows through the coil of the magnetic switch, closing it and allowing full current to flow directly to the starter motor. The ignition switch performs other jobs besides controlling the starting circuit. It normally has at least four separate positions: accessory, off, on (run), and start.

Starting Safety Switch

The **starting safety switch**, often called the **neutral safety switch**, is a normally open switch that prevents the starting system from operating when the transmission is in gear. Starting safety switches can be located between the ignition switch and the relay or solenoid or the relay and ground.

The safety switch used with an automatic transmission is normally called a park/neutral position switch (**Figure 18-25**). The switch contacts are wired in series with the control circuit so that no current can flow through the relay or solenoid unless the shift lever is in neutral or park. The switch is normally mounted on the transmission housing.

Mechanical safety switches for automatic transmissions physically block the movement of the ignition key when the transmission is in a gear. The ignition key can only be turned when the shift selector is in park or neutral. These are called interlock systems.

The safety switches used with manual transmissions are usually controlled by the clutch pedal. The clutch start switch serves the same purpose as a park/neutral position switch. The clutch start switch keeps the starter control circuit open until the clutch pedal is depressed (**Figure 18-26**).

Figure 18-25 Neutral safety switch attached to an automatic transmission.

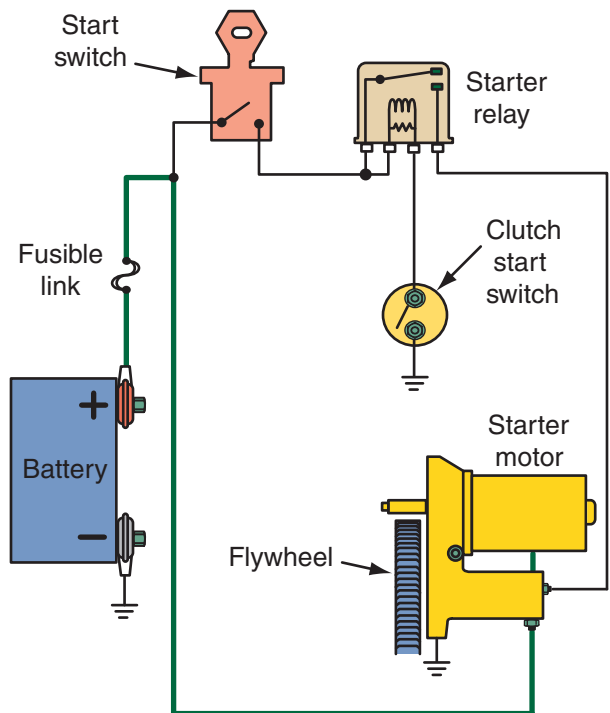

Figure 18-26 The clutch pedal must be fully depressed to close the clutch switch and complete the control circuit.

STARTING SYSTEM TESTING

As mentioned earlier, the starter motor is a special type of electrical motor designed for intermittent use only. During testing, it should never be operated for more than 15 seconds without resting for 2 minutes in between operation cycles to allow it to cool.

Preliminary Checks

The cranking output obtained from the motor is affected by the condition and charge of the battery, the circuit's wiring, and the engine's cranking requirement.

The battery should be checked and charged as needed before testing the starting system.

Check the wiring and cables for clean, tight connections. Loose or dirty connections will cause excessive voltage drops. Cables can be corroded by battery acid, and contact with engine parts and other metal surfaces can fray the cable insulation. Frayed insulation can cause a dead short that can seriously damage some of the electrical units of the vehicle.

Cables should also be checked to make sure they are not undersized or too long. When checking cables and wiring, always check the maxi-fuses and/or fusible links for the system. When one has failed, always troubleshoot the system and locate the cause before replacing the fuse or link.

Make certain that the engine is filled with proper weight oil as recommended by the vehicle manufacturer. Heavier-than-specified oil when coupled with low operating temperatures can drastically lower cranking speed to the point where the engine does not start and excessively high current is drawn by the starter.

Check the ignition switch for loose mounting, damaged wiring, sticking contacts, and loose connections. Check the wiring and mounting of the safety switch, if so equipped, and make certain the switch is properly adjusted. Check the mounting, wiring, and connections of the magnetic switch and starter motor. Also, be sure the starter pinion is properly adjusted.

Safety Precautions

Almost all starting system tests must be performed while the starter motor is cranking the engine. However, the engine must not start and run during the test or the readings will be inaccurate.

To prevent the engine from starting, the ignition switch can be bypassed with a remote starter switch that allows current to flow to the starting system but not to the ignition system.

During testing, be sure the transmission is out of gear during cranking and the parking brake is set. When servicing the battery, always follow safety precautions. Always disconnect the battery ground cable before making or breaking connections at the system's relay, solenoid, or starter motor.

SHOP TALK

Always approach starting system diagnosis in a logical way. This is the only way to identify the exact cause of a problem. Nearly 80% of starters returned as defective on warranty claims work perfectly when tested. This is often caused by poor or incomplete diagnosis of the starting and related charging systems.

Starter Solenoid Problems

A typical symptom of solenoid problems is a clicking noise when the ignition switch is turned to the start position. The noise is caused by the solenoid's plunger moving back and forth. Normally the plunger moves to the battery contacts and is held there by a magnetic field until the ignition switch is moved from the start position.

In order for the solenoid's plunger to move enough to complete the starter motor circuit and remain in that position, a strong magnetic field must be present around the solenoid's windings. The

strength of the magnetic field depends on the current flowing through the windings. Therefore, anything that would reduce current flow would affect the operation of the solenoid. Common causes of the clicking are low battery voltage, low voltage available to the solenoid, or an open in the hold-in winding.

Checking voltage at the battery and to the solenoid will help you identify the cause of the problem. If the solenoid is bad, it can be replaced as a unit or with the starter motor.

Starting Safety Switches

Safety switches can be checked with a voltmeter or an ohmmeter. When the transmission is placed in park or neutral or when the clutch pedal is depressed, the switch should be closed. In other gear positions and when the clutch pedal is released, the switch should be open. Often these switches just need to be properly adjusted to correct their action. This is not possible on all vehicles. If adjustment does not correct the problem, the switch should be replaced.

Battery Load Test

A slow cranking engine is often caused by insufficient current from the battery. The battery must be able to crank the engine under all load conditions while maintaining enough voltage to supply ignition current for starting. Perform a battery load test before checking the starting systems.

Chapter 17 for the correct procedures for conducting a battery load and other battery tests.

Cranking Voltage Test

The **cranking voltage test** measures the available voltage to the starter during cranking. To perform the test, disable the ignition or use a remote starter switch to bypass the ignition switch. Normally, the remote starter switch leads are connected to the positive terminal of the battery and the starter terminal of the solenoid or relay (**Figure 18–27**). Refer to the service manual for specific instructions on the model car being tested. Connect the voltmeter's negative lead to a good chassis ground. Connect the positive lead to the starter motor feed at the starter relay or solenoid. Activate the starter motor and observe the voltage reading. Compare the reading to the specifications given in the service manual. Normally, 9.6 volts is the minimum required.

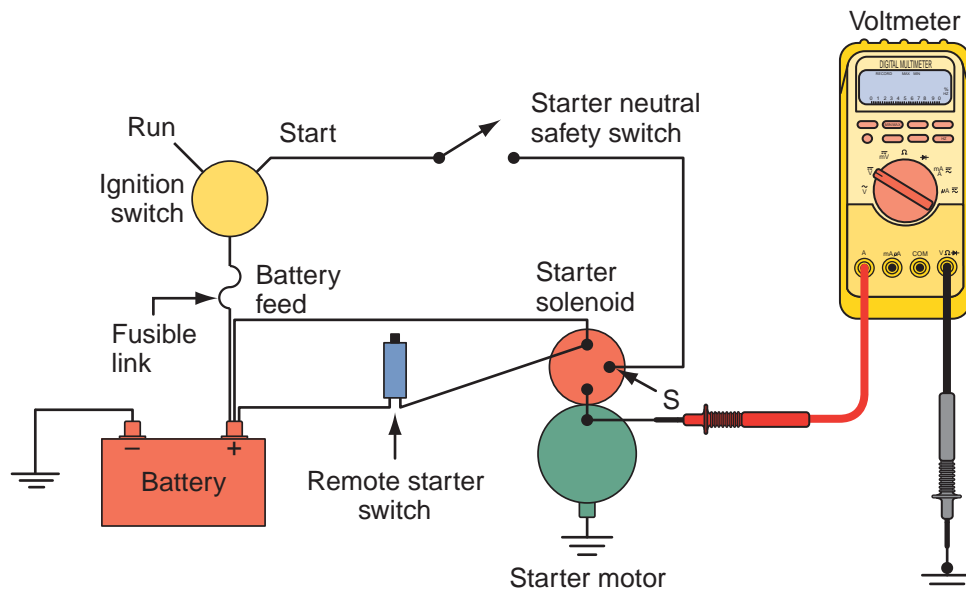

Figure 18-27 Using a remote starter switch to by pass the control circuit and ignition system.

SHOP TALK

Although most literature states that cranking voltage should be at least 9.6 volts, some engines will have a difficult time starting with voltages lower than 10.2 volts. Always check the manufacturer's specifications before coming to conclusions from this test.

Test Conclusions If the reading is above specifications but the starter motor still cranks poorly, the starter motor is faulty. If the voltage reading is lower than specifications, a cranking current test and circuit resistance test should be performed to determine if the problem is caused by high resistance in the starter circuit or an engine problem.

Cranking Current Test

The **cranking current test** measures the amount of current the starter circuit draws to crank the engine.

Nearly all starter current testers use an inductive pickup (**Figure 18-28**) to measure the current draw.

To conduct the cranking current test, connect a remote starter switch or disable the ignition prior to testing. Follow the instructions given with the tester when connecting the test leads. Crank the engine for no more than 15 seconds. Observe the voltmeter. If the voltage drops below 9.6 volts, a problem is indicated. Also, watch the ammeter and compare the reading to specifications.

Table 18-1 summarizes the most probable causes of too low or high starter motor current draw. If the

Figure 18-28 It is important to remember to move the inductive lead to the vehicle's system after checking the battery.

problem appears to be caused by excessive resistance in the system, conduct an insulated circuit resistance test.

Insulated Circuit Resistance Test

The starter circuit is made up of the insulated circuit and the ground circuit. The insulated circuit includes all of the high current cables and connections from the battery to the starter motor.

TABLE 18-1 INTERPRETING THE RESULTS OF A CRANKING CURRENT TEST

Concern	Probable Cause
Low current draw	Undercharged or bad battery Excessive resistance in the starter circuit Excessive resistance in the starter or solenoid Excessive resistance at the various connections to the starter and/or solenoid
High current draw	The starter motor is shorted A short-to-ground in the starter circuit High mechanical resistance due to engine problems Misalignment of starter drive

To test the insulated circuit for high resistance, disable the ignition or bypass the ignition switch with a remote starter switch. Connect the positive (+) lead of the voltmeter to the battery's positive (+) terminal post or nut. Connect the negative (–) lead of the voltmeter to the starter terminal at the solenoid or relay. Crank the engine and record the voltmeter reading. If the reading is within specifications (usually 0.2 to 0.6 voltage drop), the insulated circuit does not have excessive resistance. Proceed to the ground circuit resistance test outlined in the next section. If the reading indicates a voltage loss above specifications, move the negative lead of the tester progressively closer to the battery, cranking the engine at each test point. Normally, a voltage drop of 0.1 volt is the maximum allowed across a length of cable.

Photo Sequence 15 goes through the correct procedure for conducting a voltage drop test on a typical starter circuit.

Test Conclusions When excessive voltage drop is observed, the trouble is located between that point and the preceding point tested. It is either a damaged cable or poor connection, an undersized wire, or possibly a bad contact assembly within the solenoid. Repair or replace any damaged wiring or faulty connections.

Starter Relay By-Pass Test

The starter relay by-pass test is a simple way to determine if the relay is operational. First, disable

the ignition. Connect a heavy jumper cable between the battery's positive (+) terminal and the starter relay's starter terminal. This bypasses the relay. When the connection is made, the engine should crank.

CAUTION!

Make sure the vehicle's transmission is in park or neutral before doing this test. The starter motor can move the vehicle, which could injure you and others around you.

Test Conclusions If the engine cranks with the jumper installed and did not before the relay was bypassed, the starter relay is defective and should be replaced.

Ground Circuit Resistance Test

The ground circuit provides the return path to the battery for the current supplied to the starter by the insulated circuit. This circuit includes the starter-to-engine, engine-to-chassis, and chassis-to-battery ground terminal connections.

To test the ground circuit for high resistance, disable the ignition, or bypass the ignition switch with a remote starter switch. Refer to **Figure 18-29** for the proper test connection. Crank the engine and record the voltmeter reading.

Figure 18-29 Setup for checking voltage drop across the ground circuit.

Voltage Drop Testing of a Starter Circuit

P15-1 The tools required to measure voltage drop at various points within the starter circuit are fender covers, a DMM, and a remote starter switch. Make sure to apply the parking brake and set the transmission into neutral or park.

P15-2 Connect the meter's positive lead to the positive battery post. If at all possible, do not connect it to the battery clamp.

P15-3 Connect the negative lead to the battery connection at the starter.

P15-4 Set the voltmeter to the scale that is close to, but greater than, battery voltage.

P15-5 Disable the ignition and fuel injection and/or connect a remote starter switch.

P15-6 Crank the engine and read the voltmeter. This reading shows the voltage drop on the positive side of the starter circuit.

P15-7 This reading shows excessive resistance. To locate the resistance, move the meter's negative lead to the next location toward the battery. In this case it is the starter side of the starter relay.

Voltage Drop Testing of a Starter Circuit (*continued*)

P15-8 Crank the engine and observe the reading on the meter. This is the voltage drop across the positive circuit from the battery to the output of the relay.

P15-9 There is still too much voltage drop; continue the test by moving the negative lead to the battery side of the relay.

P15-10 Crank the engine and observe the reading on the meter. This is the voltage drop across the cable from the battery to the relay. Notice that hardly any voltage was dropped. This cable is okay.

P15-11 Now connect the meter across the relay: the red lead on the battery side and the black lead on the starter side.

P15-12 Crank the engine and observe the reading on the meter. This is the voltage drop across the contacts inside the relay.

P15-13 The reading is higher than normal; therefore, the starter relay has high resistance and needs to be replaced.

Test Conclusions Good results would be less than a 0.2 volt drop for a 12-volt system. A voltage drop in excess of this indicates the presence of a poor ground circuit connection, resulting from a loose starter motor bolt, a poor battery ground terminal post connector, or a damaged or undersized ground system wire from the battery to the engine block. Isolate the cause of excessive voltage drop in the same manner as recommended in the insulated circuit resistance test by moving the positive (+) voltmeter lead progressively closer to the battery. If the ground circuit tests out satisfactorily and a starter problem exists, move on to the control circuit test.

Voltage Drop Test of the Control Circuit

The control circuit test examines all the wiring and components used to control the magnetic switch, whether it is a relay, a solenoid acting as a relay, or a starter motor-mounted solenoid.

High resistance in the solenoid switch circuit reduces current flow through the solenoid windings, which can cause improper functioning of the solenoid. In some cases of high resistance, it may not function at all. Improper functioning of the solenoid switch generally results in the burning of the solenoid switch contacts, causing high resistance in the starter motor circuit.

Check the vehicle wiring diagram, if possible, to identify all control circuit components. These normally include the ignition switch, safety switch, the starter solenoid winding, or a separate relay.

To perform the test, disable the ignition system. Connect the positive meter lead to the battery's positive terminal and the negative meter lead to the starter switch terminal on the solenoid or relay. Crank the engine and record the voltmeter reading.

Test Conclusions Generally, good results would be less than 0.5 volt, indicating that the circuit condition is good. If the voltage reading exceeds 0.5 volt, it is usually an indication of excessive resistance. However, on certain vehicles, a slightly higher voltage loss may be normal.

Identify the point of high resistance by moving the negative test lead back toward the battery's positive terminal, eliminating one wire or component at a time.

A reading of more than 0.1 volt across any one wire or switch is usually an indication of trouble. If a high reading is obtained across the safety switch used on an automatic transmission, check the adjustment of the switch according to the manufacturer's service manual. Clutch-operated safety switches cannot be adjusted. They must be replaced.

Test Starter Drive Components

This test detects a slipping starter drive without removing the starter from the vehicle. First, disable the ignition system or bypass the ignition switch with a remote starter switch. Turn the ignition switch to start and hold it in this position for several seconds. Repeat the procedure at least three times to detect an intermittent condition.

Test Conclusions If the starter cranks the engine smoothly, that is an indication that the starter drive is functioning properly. If the engine stops cranking and the starter spins noisily at high speed, the drive is slipping and should be replaced.

If the drive is not slipping, but the engine is not being cranked, inspect the flywheel for missing or damaged teeth. Remove the starter from the vehicle and check its drive components. Inspect the pinion gear teeth for wear and damage. Test the overrunning clutch mechanism. If good, the overrunning clutch should turn freely in one direction but not in the other. A bad clutch will turn freely in the overrun direction or not at all. If a drive locks up, it can destroy the starter by allowing the starter to spin at more than 15 times engine speed.

Removing the Starter Motor

If your testing indicates that the starter must be removed, the first step is to disconnect the negative cable at the battery and wrap the clamp with electrical tape. It may be necessary to place the vehicle on a lift to gain access to the starter. Before lifting the vehicle, disconnect all wires, fasteners, and so on that can be reached from under the hood.

Disconnect the wires leading to the solenoid terminals. To avoid confusion when reinstalling the starter, it is wise to mark the wires so they can be reinstalled on their correct terminals.

On some vehicles you may need to disconnect the exhaust system to be able to remove the starter. Loosen the starter mounting bolts and remove all but one. Support the starter while removing the remaining bolt. Then pull the starter out and away from the flywheel. Once the starter is free, remove the last bolt and the starter.

Once the starter is out, inspect the starter drive pinion gear and the flywheel ring gear (**Figure 18-30**). When the teeth of the starter drive are abnormally worn, make sure you inspect the entire circumference of the flywheel. If the starter drive or the flywheel ring gear show signs of wear or damage, they must be replaced.

PINION AND RING GEAR WEAR PATTERNS

Free Speed (No-Load) Test

Every starter should be bench tested after it is removed and before it is installed. To conduct a free speed or no-load test on a starter, follow these steps:

PROCEDURE

Free Speed or No-Load Test

- STEP 1** Clamp the starter firmly in a bench vise.
- STEP 2** Connect an ammeter to the battery cable and the starter to a battery. This should cause the motor to run.
- STEP 3** Check current draw and motor speed and compare them to specifications. If they meet specs when the battery has at least 11.5 volts, the starter is working properly.

If the current draw was excessive or the motor speed too low, there is excessive physical resistance,

which can be caused by worn bushings or bearings, a shorted armature, shorted field windings, or a bent armature.

If there was no current draw and the starter did not rotate, the problem could be caused by open field windings, open armature coils, broken brushes, or broken brush springs.

Low armature speed with low current draw indicates excessive resistance. There may be a poor connection between the commutator and the brushes, or the connections to the starter are bad. If the speed and current draw are both high, check for a shorted field winding.

STARTER MOTOR SERVICE

If the starter is bad, it should be replaced or rebuilt. Often technicians opt for replacing it rather than spending the time to repair or rebuild it. This decision, however, depends on a number of things, including the customer's desire, shop's policies, availability of repair parts, cost, and time.

Photo Sequence 16 covers the typical procedure for disassembling a Delco-Remy starter. Always refer to the manufacturer's procedures when repairing a starter.

WARNING!

Do not clean the starter motor in solvent. The residue left on the parts can ignite and cause a fire and/or destroy the starter. Use denatured alcohol, compressed air regulated to 25 psi (172.3 kPa), and/or clean rags to clean the unit and its parts.

The starter should be cleaned and inspected as it is disassembled. Inspect the end frame and drive housing for cracks or broken ends. Check the frame assembly for loose pole shoes and broken or frayed wires. Inspect the drive gear for worn teeth and proper overrunning clutch operation. The commutator should be free of flat spots and should not be excessively burned. Check the brushes for wear. Replace them if worn past specifications.

Starter Motor Component Tests

With the starter motor disassembled, tests can be conducted to determine the reason for failure. The armature and field coils should be checked for shorts and opens first. Normally, if the armature or coils are bad, the entire starter is replaced.

Typical Procedure for Disassembling a Delco-Remy Starter

P16-1 Always have a clean and organized work area. The tools required for disassembling this starter are: rags, assorted wrenches, snapping pliers, flat blade screwdriver, ball-peen hammer, plastic head hammer, punch, scribe, safety glasses, and small press.

P16-2 Clean the case.

P16-3 Scribe reference marks at each end of the starter end housings and the frame.

P16-4 Disconnect the field coil connection at the solenoid's M terminal.

P16-5 Remove the two screws that attach the solenoid to the starter drive housing.

P16-6 Rotate the solenoid until the locking flange of the solenoid is free. Then remove the solenoid.

P16-7 Remove the through-bolts from the end frame.

Typical Procedure for Disassembling a Delco-Remy Starter (continued)

P16-8 Remove the end frame.

P16-9 Remove the frame.

P16-10 Remove the armature.
Note: On some units it may be necessary to remove the shift lever from the drive housing before removing the armature.

P16-11 Place a $\frac{5}{8}$ -inch deep socket over the armature shaft until it contacts the retaining ring of the starter drive.

P16-12 Tap the end of the socket with a plastic-faced hammer to drive the retainer toward the armature. Move it only far enough to access the snapping.

P16-13 Remove the snapping.

P16-14 Remove the retainer from the shaft and remove the clutch and spring from the shaft. Press out the drive housing bushing and the end-frame bushing.

Figure 18-31 Checking a field coil for an open.
Courtesy of Toyota Motor Sales, U.S.A., Inc.

Field Coil Tests The field coil and frame assembly can be wired in a number of different ways. Accurate testing of the coils can only be done if you follow the specific guidelines of the manufacturer or if you know how the coils are wired. To do this, look at the wiring diagram and figure out where the coils get their power and where they ground. When you have this information, you will know if the coils are wired in series or parallel.

The usual way to check the field coils for opens is to connect an ohmmeter between the coils' power feed wire and the field coil brush lead (**Figure 18-31**). If there is no continuity, the field is open. To check the field coil for a short to ground, connect the ohmmeter from the field coil brush lead and the starter (field frame) housing. If there is continuity, the field coil is shorted to the housing.

Armature Tests The armature should be inspected for wear or damage caused by contact with the permanent magnets or field windings. If there is wear or damage, check the pole shoes for looseness and repair as necessary. A damaged armature must be replaced.

Next, check the commutator of the armature. If the surface is dirty or burnt, clean it with emery cloth or cut it down with an armature lathe. Measure the diameter of the commutator with an outside micrometer or vernier caliper. If the diameter is less than specifications require, replace the armature.

Measure commutator runout by mounting the armature in V-blocks. Position a dial indicator so that it rides on the center of the commutator. If the runout is within specs, check the commutator for carbon dust or brass chips between the segments. If the commutator runout is beyond specs, replace the armature.

Check the depth of the insulating material (mica) between the commutator segments. Check each one and compare the depth with specifications. If necessary, undercut the mica with the proper tool or a

Figure 18-32 Checking the armature for an open.
Courtesy of American Isuzu Motors Inc.

Figure 18-33 Testing an armature on a growler.

hacksaw to achieve the proper depth. If the proper depth cannot be achieved, replace the armature.

Check for continuity between the segments of the commutator (**Figure 18-32**). If an open circuit exists between any segments, replace the armature.

Place the armature in an armature tester, commonly called a **growler**. Hold a hacksaw blade on the armature core (**Figure 18-33**). If the blade is attracted to the armature's core or vibrates while the core is turned, the armature is shorted and must be replaced.

With an ohmmeter, check the armature windings for a short to ground. Hold one meter lead to a commutator segment and the other on the armature core. Also check between the armature shaft and the commutator. If there is continuity at either of these two test points, the armature needs to be replaced.

Brush Inspection Brush inspection begins with an ohmmeter check of the brush holder. Connect one meter lead to a positive brush and the other lead to a negative brush. There should be no continuity between them. If there is, replace the brush holder. Install the brushes into the brush holder and slip the unit over the commutator. Using a spring scale, measure the spring tension of the holders at the moment the spring lifts off the brush. Compare the tension

Brush holder side

Field frame side

Figure 18-34 Measure the length of the brushes.
 Courtesy of Toyota Motor Sales, U.S.A., Inc.

with specs. If the tension is incorrect, replace the spring or the brush holder assembly.

Measure the length of the brushes (**Figure 18-34**). If the brushes are not within specs, replace the brush or the brush holder assembly. To seat new brushes after installing them in the brush holder, slip a piece of fine sandpaper between the brush and the commutator. Then rotate the armature. This will put the contour of the commutator on the face of the brushes.

Bearings and Bushings Check each bearing and bushing by placing the armature into the bushing and paying attention to the fit and feel as the armature is rotated in the bushing. If the bushing or bearing feels too loose, tight, or rough, it should be replaced. Bushings can often be visually inspected for uneven and excessive wear. If the bushing is bad, replace it. Many bearings are held in the case by a retainer, while bushings are typically pressed out and into their bore.

Starter Drives and Clutches Carefully inspect the teeth on the starter drive. If the teeth are chipped, excessively worn, or damaged in any way, replace the drive assembly. Also check the teeth on the starter ring gear on the engine's flywheel. Often the same

Figure 18-35 Check the overrunning clutch by attempting to rotate it in both directions.

thing that caused damage to the starter drive will damage the teeth on the flywheel. If either or both are damaged, they should be replaced.

To check the operation of the overrunning clutch, slide the drive and clutch assembly onto the armature shaft. Rotate the clutch in both directions. Check its movement. It should rotate smoothly in one direction and lock in the other (**Figure 18-35**). If it does not lock in either direction or if it locks or barely moves in both directions, the assembly must be replaced.

CASE STUDY

A vehicle equipped with a solenoid-actuated direct-drive starting system is towed into the shop. The owner complains that the starter does not crank the engine when the ignition switch is turned to the start position.

The technician performs a battery load test to confirm that the battery is in good working order. It is. The technician then tests for voltage to the M or motor terminal on the solenoid using a voltmeter. Voltage reading at the M terminal is 12.5 volts.

Because there is voltage at the M terminal of the solenoid, inspection of individual connections and components, such as the starter safety switch, are not needed at this time. They are obviously allowing current to pass through the insulated circuit.

The technician then performs a ground circuit check to verify that the ground return path is okay. It is. Since the insulated and ground circuits have checked out okay, the only other source of an open circuit is the starter motor. The technician can now confidently pull the starter motor from the vehicle for rebuilding or replacement.

Starter Motor Reassembly

To reassemble the starter, basically reverse the disassembly procedures. Additional guidelines for reassembly follow:

- Lubricate the splines on the armature shaft that the drive gear rides on with a high-temperature grease.
- Lubricate the bearings and/or bushings with a high-temperature grease.
- Apply sealing compound to the solenoid flange before installing the solenoid to the starter motor.
- Check the pinion depth clearance.
- Perform a no-load test on the starter before installing it.

Installation

When installing a new or remanufactured starter, sand away the paint at the mounting point before installing it. Also, make sure you have a good hold on the starter while installing it. Tighten the retaining bolts to the specified torque and make sure the starter is fully seated before final tightening. Also, make sure that all electrical connections are tight. If the starter was installed with heat shields, make sure they are in place before tightening the bolts.

Some starters use shims between the starter and the mounting pad (**Figure 18-36**). To check this clearance, install the starter and insert a flat blade screwdriver into the access slot on the side of the drive

A 0.015-inch (0.381 mm) shim will increase the clearance by approximately 0.005 inch (0.1270 mm).

Figure 18-36 Shimming the starter to obtain proper pinion-to-ring gear clearance.

housing. Pry the drive pinion gear into the engaged position. Use a wire feeler gauge or a piece of 0.020-inch diameter wire to check the clearance between the gears (**Figure 18-37**).

If the clearance between the two gears is incorrect, shims will need to be added or subtracted to bring the clearance within specs. If the clearance is excessive, the starter will produce a high-pitched whine while it is cranking the engine. If the clearance is too small, the starter will make a high-pitched whine after the engine starts and the ignition switch is returned to the RUN position.

Figure 18-37 Checking the clearance between the pinion gear and the ring gear.

HIGH-VOLTAGE MOTORS

Hybrid and fuel cell vehicles use strong electric motors to move the vehicle and, in some cases, to start the engine as well. Often hybrid vehicles also have a normal starting motor, which may only serve as a back-up unit (**Figure 18-38**). These starting motors are conventional and are not part of this discussion.

High-voltage motors are used for many purposes and in many different systems. They may be used to drive the air-conditioning compressor, work as a starting motor, or power the vehicle. The latter motors are referred to as traction motors.

Traction Motors

The placement and purpose of a **traction motor** depends on the design of the hybrid. All are powered by more than 12 volts. On some models, the high-voltage motor is not capable of moving the vehicle by itself. Instead it merely works as a starter motor and generator or adds power to the output of the engine. How these motors function as a generator is discussed in Chapter 19. Different motor designs are used as traction motors. A few are powered by DC voltage but most use AC.

The motors can be liquid or air cooled and are normally lubricated for life. Most production vehicles

use AC motors, and many conversion electric vehicles use a DC motor. The latter is a consequence of cost. DC motors can be powered directly by the batteries, whereas AC motors require converters and inverters to change the DC voltage stored in the batteries into the AC required by the motors.

DC electric motors are quite reliable, but the brushes and commutator present some durability concerns. The carbon brushes spark and wear out, and the spring tension on the brushes must be kept within specifications. Excessive spring tension causes excessive friction and wear of the brushes and commutator. When the spring tension is too low, sparking occurs between the brush and the commutator, causing damage to both, and the brushes can bounce, which makes and breaks the circuit. Both of these problems can result in overheating the motor and decreasing reliability. Although brushless DC motors do not have this problem, most cannot provide enough power to move a vehicle.

DC motors are typically more expensive than comparable AC motors. In addition, the available torque from a DC motor is at its peak when the rotor or armature is not turning. The available torque decreases from that peak as armature speed increases. DC motors also tend to run hotter; therefore, they need proper cooling. DC motors also do not provide for regenerative braking unless they are separately excited (Sep-Ex) DC motors fitted with a special controller that allows for efficient switching of the motor to a generator and back to a motor.

AC motors are lighter than comparable DC motors. They are also very reliable. Because they have only one moving part, the shaft, they should last the life of the vehicle with little or no maintenance. In an AC motor, there is no commutator to distort or burn and no brushes to wear or spark.

AC systems typically operate at higher voltage and lower current than DC systems with the same power output. In an AC induction motor, the torque output is constant through a wide range of speeds. This provides even acceleration and often allows driving without the need of a transmission and different speed gears. There is no need for additional controllers or electronics to have regenerative braking.

The primary disadvantage of an AC motor is, again, the cost of the electronic systems required to convert (invert) the battery's DC to AC for the motor. However, most electronic equipment is becoming less expensive (as well as better), and this disadvantage has less merit than it did a few years ago and will be less of a consideration in the future. Manufacturers used AC motors simply because of their efficiency and lighter weight.

Figure 18-38 This electric motor, attached directly to the engine's crankshaft, starts the engine under normal conditions. When outside temperature is extremely low, when the battery state of charge is low, or if there is a problem with the hybrid system, the conventional starter starts the engine.

The addition of an electric motor or motors to the driveline is what makes a hybrid vehicle fuel efficient. The motor provides full torque at low speeds, which helps with good acceleration, and uses zero fuel when it is operating on its own. The intervention of the electric motor allows for the use of a smaller, more efficient engine. Although the engine is designed for fuel economy, it alone cannot provide adequate power for safe acceleration and load overtaking. The motors also have low production costs, low noise, and high efficiency. The electric motor can be configured, through electronics, to assist the engine during acceleration, passing, overtaking heavy loads, or hill climbing. Advanced electronics allow the motor to act as a generator when its power is not needed. The hybrid controller or computer-controlled system coordinates or synchronizes the action of both.

Brushless DC Motors

A brushless DC motor is much like a brushed DC motor, but the purpose of the rotor (armature) and stator (field windings) are reversed. The rotor has a set of permanent magnets and the stator has controllable electromagnets (Figure 18-39). Obviously, a brush-

Figure 18-39 A brushless DC motor.

less motor has no brushes and no commutator. The normal electrical arcing that takes place between the brushes and commutator is eliminated with the brushless design. This arcing not only decreases the usable life of a motor, it also creates electromagnetic interference that is detrimental to advanced electronic systems.

Rather than using brushes, an electronic circuit switches current flow to the different stator's windings to keep the rotor turning. The reversing of current flow through the windings is done by power transistors that switch according to the position of the rotor. Many brushless DC motors use Hall-effect sensors to monitor the position of the rotor. Other brushless motors monitor the CEMF in unexcited field windings to determine the position of the rotor. The current to the various stator windings is typically controlled by a **pulse width modulation (PWM)** frequency inverter. The voltage to the windings is changed by altering the duty cycle.

The **duty cycle** of something is the length of time the device is turned on compared to the time it is off (Figure 18-40). Duty cycle can be expressed as a ratio or as a percentage. By quickly opening and closing the power circuit to the motor, the speed of the motor is controlled. This is called pulse width modulation. These power pulses vary in duration to change the speed of the motor. The longer the pulses, the faster the motor turns.

Brushless DC motors, when compared to brushed DC motors, are more reliable, more powerful, and more expensive. The expense is largely due to the cost of the electronic controls. High-output brushless DC motors are used in some electric drive vehicles.

AC Motors

With AC voltage, the direction of current flow changes but not immediately. Rather, as the current is getting ready to change directions, it decreases until it

Figure 18-40 The action of various duty cycles.

reaches zero and then gradually builds up in the other direction. Therefore, the amount of current in an AC circuit always varies. When AC is given as a value, it is an average rating, not peak current. This average rating is referred to as a “root mean square” value.

Basic Construction An AC motor has two basic electrical parts: a stator and a rotor. The stator is comprised of individual electromagnets electrically connected to each other or connected in groups. The rotor is the rotating magnetic field and can be an electromagnet or a permanent magnet. The rotor is located within the stator fields. Like a DC motor, the rotor rotates as a result of the repulsion and attraction of the magnetic poles. The way this works is quite different.

Basic Operation Current is passed through the stator and rotor, causing the rotor to spin. Because the current is alternating, the polarity in the windings constantly changes. A synchronous AC motor will run at the frequency of the AC voltage. Many AC motors are induction types. In these motors, electrical current is induced in the rotor as it rotates, rather than have current delivered to it from an external source.

The rotor spins because it is pulled along by a rotating magnetic field in the stator. The stator does not physically move. The magnetic field does. If the windings of the stator are wired in series, current

passes through them one at a time, and (because it is AC) the polarity and strength of the field around them are constantly changing (**Figure 18–41**). The magnetic field of the rotor reacts and moves along with the “rotating magnetic field” of the stator.

To better understand this concept, let us look at a three-phase motor. Three-phase AC voltage is commonly used in motors because it provides a smoother and more constant supply of power. Three-phase AC voltage is much like having three independent AC power sources, each with the same amplitude and frequency but are 120 degrees out of phase with each other.

To produce a rotating magnetic field in the stator, each phase of the three-phase power source is connected to separate stator windings. Because each phase reaches its peak voltage at successively later times, the magnetic field is at its strongest point in each winding in succession as well. This creates the effect of the magnetic field continually moving around the stator. This rotating magnetic field will move around the stator once for every cycle of the voltage in each phase (**Figure 18–42**). This means the field is rotating at the frequency of the source voltage. Remember that as the magnetic field moves, new magnetic polarities are present. As each polarity change is made, the poles of the rotor are attracted by the opposite poles on the stator. Therefore, as the magnetic field of the stator rotates, the rotor rotates with it.

Figure 18–41 Notice how the polarity of the stator and rotor changes over time.

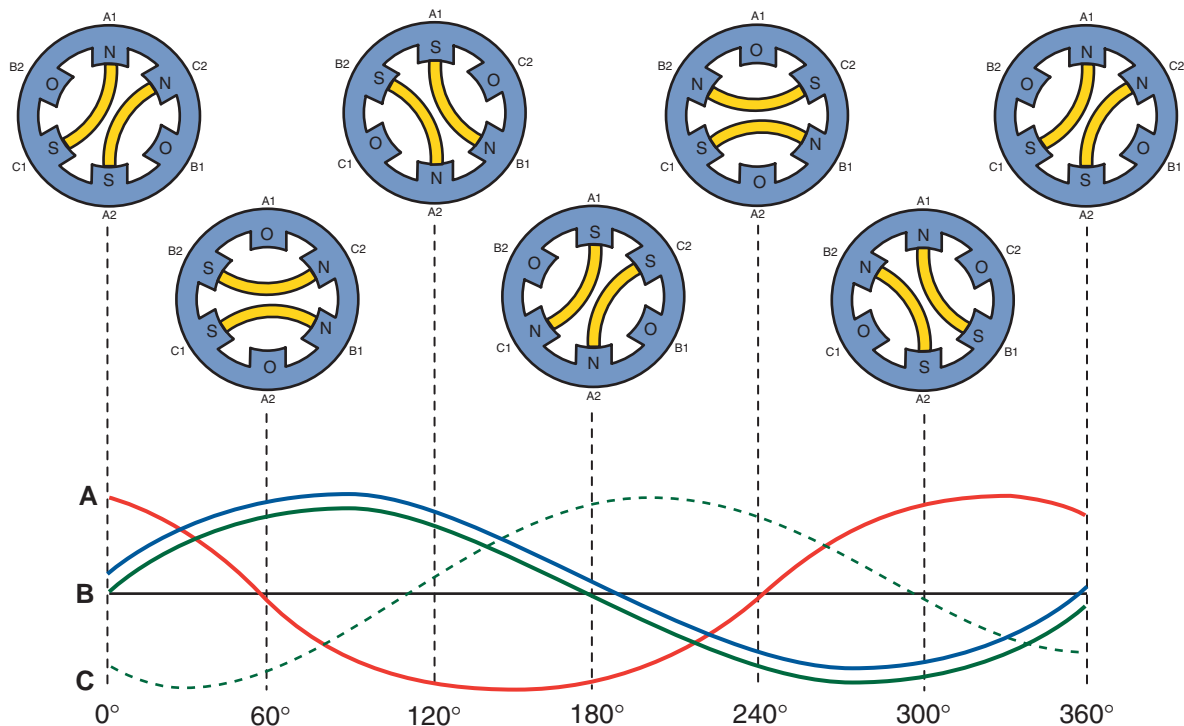

Figure 18-42 The rotor turns in response to the changing polarities caused by the three-phase AC.

Synchronous Motor

A synchronous motor (**Figure 18-43**) operates at a constant speed regardless of the load. Rotor speed is equal to the speed of the stator's rotating magnetic field. A synchronous motor is used when the exact speed of a motor must be maintained. Often, synchronous motors have magnets built into the rotor assembly. These magnets allow the rotor to easily align itself with the rotating magnetic field of the stator.

When three-phase AC is fed to the three sets of windings in the stator coil, a rotating magnetic field is

present around the stator. The rotor simply rotates with that rotating magnetic field. The torque output of the rotor, therefore, is dependent on the strength of the magnetic field around the stator. The speed of the rotor is determined by the frequency of the AC input to the stator. Synchronous motors are available with outputs up to thousands of horsepower.

One of the disadvantages of synchronous motors is that they cannot be started by merely applying three-phase AC power to the stator. When AC is applied to the stator, a high-speed rotating magnetic field is immediately present. This field rushes past the rotor so quickly that the rotor cannot get started. The rotor is first repelled in one direction and then, very quickly, in another. There are many ways of addressing this, but for hybrid and electric vehicles the problem is solved by complex electronics that begin the rotating magnetic field in such a way and speed that the rotor simply follows the field (**Figure 18-44**). Once the rotor is spinning, normal synchronous operation begins.

Figure 18-43 A synchronous motor assembly designed to fit between the engine's crankshaft and the transmission. Courtesy of Robert Bosch GmbH, www.bosch-presse.de

Asynchronous Motor

The most commonly used motor is the three-phase AC induction motor, which is most often found in hybrids. This motor has a low cost and a simple design. The stator is connected to the power source and the rotor. The three-phase AC sets up a rotating magnetic field around the stator. The rotor is not connected to an external source of voltage.

Figure 18-44 The synchronous motor used in Toyota's hybrid vehicles is controlled by the vehicle's inverter, which is part of the hybrid control system.

An induction motor generates its own rotor current. The current is induced in the rotor windings as the rotor cuts through the magnetic flux lines of the rotating stator field. The induced current causes each rotor conductor to act like the permanent magnet. As the magnetic field of the stator rotates, the magnetic field of the rotor follows the rotating magnetic field of the stator. It should be obvious that this type motor needs some rotation of the rotor before it can rotate on its own. Various methods are used to start these motors, including capacitors and separate starting windings.

It is impossible for the rotor of an induction motor to rotate at synchronous speed. If the rotor were to turn at the same speed as the rotating field, there would be no relative motion between the stator and rotor fields. As a result, no lines of force would be cut by the rotor's conductors, and there would be no induced voltage in the rotor. In an induction motor, the rotor must rotate at a speed slower than that of the rotating magnetic field. This is why these motors are called "**asynchronous motors**."

The difference between the synchronous speed and actual rotor speed is called **slip**. Slip is directly proportional to the load on the motor. When loads are on the rotor's shaft, the rotor tends to slow and slip increases. The slip then induces more current in the rotor and the rotor turns with more torque but at a slower speed; therefore, it produces less CEMF.

Asynchronous motors are used in most hybrid vehicles. Their placement can be between the engine and transmission, inside the transmission (**Figure 18-45**), or at the individual wheels. This motor offers many advantages for use in hybrid and fuel cell vehicles, one being the ease of controlling its speed. Basically its speed is determined by the frequency and amount of the voltage applied to it.

Figure 18-45 The transaxle bolted to the engine contains two separate electric motors. The object in the background is the battery pack. *Courtesy of Toyota Motor Sales, U.S.A., Inc.*

Figure 18-46 A resolver located in each motor precisely detects the magnetic pole position of the rotor and allows the control unit to monitor and control the activity of MG1 and MG2.

Rotor Sensors AC motors require a sensor to monitor the position of the rotor within the stator. It is necessary to time, or phase, the three-phase AC so it attracts the rotor's magnets and keeps it rotating and producing torque. AC creates a rotating magnetic field in the stator and the rotor chases that field. The control system monitors the position and speed of the rotor and controls the frequency of the stator's voltage, which in turn controls the torque and speed of the motor.

Toyota uses a sensor (**Figure 18-46**), called a resolver, to monitor the position of the rotor in its traction motors. The sensor has three individual coil windings: one excitation coil and two detection coils. The detection coils are electrically staggered 90 degrees. The flow of AC into an excitation coil results in a constant frequency through the coil.

This frequency is sent to the detection coils and is altered by the presence of the rotating magnetic field. Because the rotor has a slight oval shape, the gap between the stator and rotor varies as the rotor rotates. A strengthening and weakening of the magnetic field occurs with the changing gap and alters the frequency at the detection coils. The control unit determines the exact position of the rotor according to the difference between the frequency values of the detection coils. The control unit also calculates the rotational speed of the rotor based on the speed at which the position changes.

Honda has a similar device but relies on three Hall-effect sensors rather than frequency detection coils.

Inverters

All AC motors require AC voltage. In a vehicle, this can be provided directly by an AC generator or through an inverter connected to the battery, which stores DC. Fuel cells produce DC voltage that can be used to

Figure 18-47 The power inverter for a two-mode hybrid system. *Courtesy of Chrysler LLC*

power motors and lights and charge batteries without additional electronics.

A power **inverter** is used to change the battery's high-voltage DC into high-voltage, three-phase AC to power the electric motors (**Figure 18-47**). It also changes the AC generated by the motors/generators to DC so it can recharge the battery pack. The inverter is basically a three-phase parallel circuit with each leg containing two power transistors connected in series. The electronic control unit controls the power transistors to ensure proper phasing of the AC to the motors. This circuit is connected between the motor/generator and the battery pack. The inverter assembly contains one of these circuits for each of the motor/generators in the vehicle. For additional power output from the motors, some vehicles have a boost converter that provides increased voltage to the motors. In many cases, the boost voltage is twice that of the battery's nominal voltage.

Controllers

A controller is used to manage the flow of electricity from the batteries to the motors, thereby controlling their speed. A sensor located by or connected to the throttle pedal sends the driver's input to the controller. The controller then sends the appropriate amount of voltage to the motor.

A simple controller is a variable resistor or potentiometer connected to the accelerator. When there is no pressure on the accelerator, resistance of the potentiometer is too high to allow voltage to the motor. When the accelerator is fully opened, the resistance is very low and full battery voltage is delivered to the motor. The various positions of the accelerator

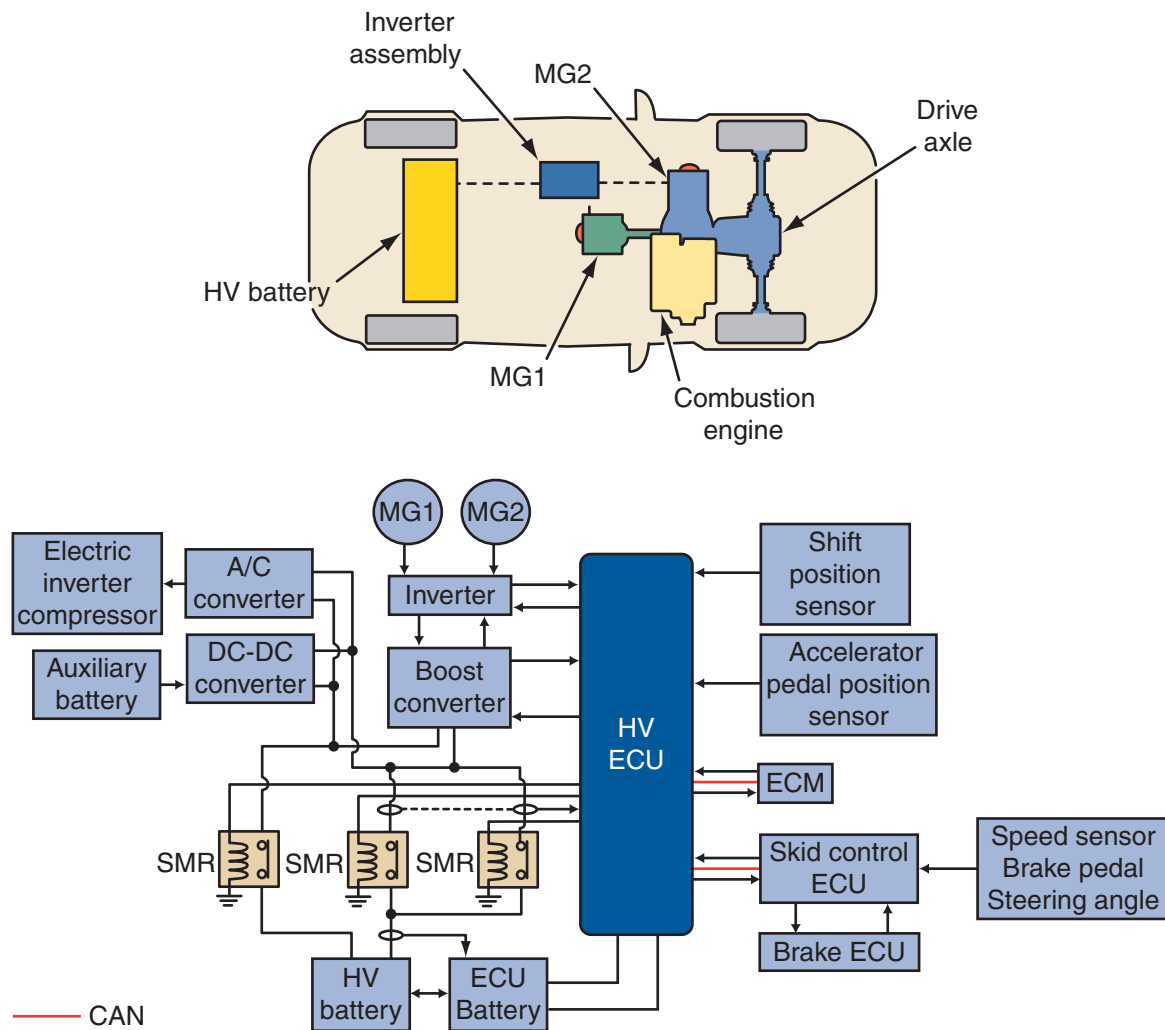

Figure 18-48 A diagram of Toyota's hybrid control system.

between closed and wide open allow corresponding amounts of voltage to the motor.

Using electronics, the same principle can be used but with more positive results. A sensor monitors the accelerator and sends information to a control unit. The control unit monitors that signal plus other inputs regarding the operating conditions of the vehicle (**Figure 18-48**). The control unit then duty cycles the voltage from the inverter to the motor. In this way, the voltage is pulsed and more precise motor speed control is possible. Most controllers pulse the voltage more than 15,000 times per second.

Stop-Start Feature

The stop-start (Honda refers to this feature as idle stop) operational mode is initiated when the car is at a stop, the shift lever is placed in neutral, the clutch pedal is released, and/or when the brake pedal is held down (**Figure 18-49**). Stop-start systems automatically shut down the engine to prevent the waste of

fuel while the engine is idling. This feature can increase fuel economy by more than 5%. Stop-start does not occur if the voltage of the battery module is low. The benefit of these systems is most evident during stop-and-go driving. The engine is restarted automatically when the driver releases the brake pedal or when the control system senses the need. Typically the traction motor is used to quickly rotate the engine to restart it.

When the engine is restarted is a defining element of mild and full hybrids. Full hybrids can be powered by only the electric motor or the gasoline engine alone, or both. They have the stop-start feature but the engine does not automatically restart when the brakes are released. Because a full hybrid can accelerate by only the electric motor, the engine is not restarted until the engine's power is needed. This is determined by the control system and is based on the vehicle's load and the batteries' state of charge.

SUMMARY

- A magnetic field, called a flux field, exists around every magnet.
- The magnetic polarity of an electromagnet depends on the direction of current flow through the loop.
- The strength of the field around an electromagnet increases if current through the coil increases, the number of coil turns increases, and the reluctance decreases.
- The basic parts of a motor are the stator or field windings, which are the stationary parts of the motor, and the rotor or armature, which is the rotating part.
- A starting motor is a special type of electric motor designed to operate under great electrical loads and to produce great amounts of torque for short periods.
- All starting motors have a housing, field coils (windings), an armature, a commutator with brushes, and end frames.
- The amount of torque from a starting motor depends on its current draw, which is controlled by CEMF.
- Current flowing through a wire creates a magnetic field around the wire. Moving a wire through a magnetic field creates current flow in the wire.

- The starting system has two distinct electrical circuits: the starter circuit and the control circuit.
- The starter circuit carries high current flow from the battery through heavy cables to the starter motor.
- The control circuit uses a small amount of current to operate a magnetic switch that opens and closes the starter circuit.
- The ignition switch is used to control current flow in the control circuit.
- Solenoids and relays are the two types of magnetic switches used in starting systems. Solenoids use electromagnetic force to pull a plunger into a coil to close the contact points. Relays use a hinged armature to open and close the circuit.
- The drive mechanism of the starter motor engages and turns the flywheel to crank the engine for starting.
- An overrunning clutch protects the starter motor from spinning too fast once the vehicle engine starts.
- Starting safety switches prevent the starting system from operating when the transmission is engaged.
- Battery load, cranking voltage, cranking current, insulated circuit resistance, starter relay bypass, ground circuit resistance, control circuit, and drive component tests are all used to troubleshoot the starting system.
- With the starter removed, inspect the starter drive pinion gear and the flywheel ring gear.
- The starter should be cleaned and inspected as it is disassembled.
- The housing, end frames, field coils, armature, brushes, and drive should be carefully inspected.
- Hybrid and fuel cell vehicles use strong electric motors to move the vehicle, and in some cases, to start the engine as well.
- The placement and purpose of a traction motor depends on the design of the hybrid.
- A brushless DC motor is much like a brushed DC motor, but the purpose of the rotor (armature) and stator (field windings) are reversed.
- In an AC motor, the polarity in the windings constantly changes. Most AC motors use three-phase AC.
- A synchronous AC motor will run at the frequency of the AC voltage.

- An asynchronous motor cannot run at the frequency of the voltage, and its speed is controlled by the frequency and amount of voltage applied to it.
- AC motors require a sensor to monitor the position of the rotor within the stator. It is necessary to time, or phase, the three-phase AC so it attracts the rotor's magnets and keeps it rotating and producing torque.
- An inverter is used to change the battery's high-voltage DC into high-voltage, three-phase AC to power the electric motors.
- The stop-start operational mode turns off the engine when the car is at a stop and quickly restarts it when it is needed.

REVIEW QUESTIONS

1. *True or False?* The strength of the magnetic poles in an electromagnet decreases with an increase in the number of turns of wire and the current flowing through them.
2. What is three-phase AC and why is it used for many motors?
3. Briefly explain the differences between a brushed and a brushless DC motor.
4. *True or False?* Many armature bearings are held in the case by a retainer, whereas bushings are typically pressed out and into their bore.
5. Which of the following is *not* part of the starter circuit?
 - a. battery
 - b. starting safety switch
 - c. starter motor
 - d. relay solenoid
6. Which of the following tests would *not* be performed to check for high resistance in the battery cables?
 - a. cranking voltage test
 - b. insulated circuit resistance test
 - c. starter relay by-pass test
 - d. ground circuit resistance test
7. When the starter spins but does not engage the flywheel, which of the following may be true?
 - a. defective starter drive
 - b. excessive resistance in the control circuit
 - c. a faulty starter relay
 - d. all of the above

8. If the solenoid clicks while trying to crank the engine with the starter, which of the following is *not* a probable cause?
 - a. a faulty neutral safety switch
 - b. low battery voltage
 - c. low voltage available to the solenoid
 - d. an open in the hold-in winding
9. The normal minimal cranking voltage specification is approximately _____.
 - a. 9.6 volts
 - b. 10.5 volts
 - c. 11.0 volts
 - d. 12.65 volts
10. If a ground circuit test reveals a voltage drop of more than 0.2 volt, the problem may be _____.
 - a. a loose starter motor mounting bolt
 - b. a poor battery ground terminal post connector
 - c. a damaged battery ground cable
 - d. all of the above
11. Which of the following would *not* cause excessive current draw by the starter motor?
 - a. a short in the motor
 - b. high resistance in the armature
 - c. using oil that is too heavy in the engine
 - d. very cold weather
12. The device that prevents the engine from turning the armature of the starter motor is the _____.
 - a. overrunning clutch
 - b. pinion gear
 - c. flywheel
 - d. pole shoe
13. The part of the armature that the brushes ride on is called the _____.
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
14. What is a synchronous motor?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
15. A control circuit test may uncover which of the following conditions?
 - a. high resistance in the solenoid switch circuit
 - b. worn brushes
 - c. loose battery cable connection
 - d. short in the starter armature windings
2. While discussing armature testing: Technician A says to test for shorts, place the armature in a growler, and hold a thin metal blade parallel to the armature. If the blade vibrates while the armature is turned, there is a short. Technician B says that an ohmmeter can be used to test for shorts. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
3. Pinion gear-to-flywheel ring gear clearance is being discussed: Technician A says that if there is too much clearance there will be a high pitch while the engine cranks. Technician B says that if there is too little clearance, there will be a high pitch while the starter is cranking the engine. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
4. Technician A says that a starter no-load test is conducted with the starter in a bench vise. Technician B says that the no-load test is similar to an open-circuit voltage test. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
5. Technician A checks a starter's field coils for opens by connecting an ohmmeter between the coils' power feed wire and the field coil brush lead. Technician B checks a starter's field coil for a short to ground by connecting an ohmmeter across the field coil brush lead and the starter housing. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
6. Technician A says that the purpose of the starter relay is to complete the circuit from the battery to the starter motor. Technician B says that the purpose of the solenoid is to complete the circuit from the battery to the starter motor. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
7. While discussing the stop-start feature of hybrid vehicles: Technician A says that it is initiated when the car is at a stop, the shift lever is placed in neutral, the clutch pedal is released, and/or when the brake pedal is held down. Technician B says that stop-start does not occur if the voltage of the high-voltage battery's state-of-charge is low. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B

ASE-STYLE REVIEW QUESTIONS

1. An engine cranks slowly: Technician A says that a possible cause of the problem is poor starter circuit connections. Technician B says that an engine problem could be the cause. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B

8. While discussing asynchronous motors: Technician A says that the speed of the motor stays constant regardless of the load put on it. Technician B says that their speed is determined by the frequency and amount of the voltage applied to them. Who is correct?
- a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
9. While discussing DC starting motors: Technician A says that the armature may be wired in series with the field coils. Technician B says that the field coils may be wired parallel with the armature. Who is correct?
- a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
10. While discussing electric motors: Technician A says that when there is high CEMF, there will be high current flow. Technician B says that if the reluctance of an electromagnet increases, its field strength increases. Who is correct?
- a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B

CHARGING SYSTEMS

OBJECTIVES

- Explain the purpose of the charging system.
- Identify the major components of the charging system.
- Explain the purposes of the major parts of an AC generator.
- Explain half- and full-wave rectification and how they relate to AC generator operation.
- Identify the different types of AC voltage regulators.
- Describe the two types of stator windings.
- Explain the features enabled by the use of a starter/generator unit.
- Perform charging system inspection and testing procedures using electrical test equipment.

The primary purpose of a charging system is to recharge the battery. After the battery has supplied the high current needed to start the engine, the battery, even a good battery, has a low charge. The charging system recharges the battery by supplying a constant and relatively low charge to the battery. Charging systems work on the principles of magnetism to change mechanical energy into electrical energy. This is done by inducing voltage.

Voltage is induced in a wire when it moves through a magnetic field. The wire or conductor becomes a source of electricity and has a polarity or distinct positive and negative ends. However, this polarity can be switched depending on the relative direction of movement between the wire and magnetic field (Figure 19-1). This is why an AC generator produces alternating current (Figure 19-2).

Figure 19-1 Moving a conductor so it cuts across the magnetic lines of force induces a voltage in the conductor.

Figure 19-2 An AC generator. Courtesy of Robert Bosch GmbH, www.bosch-presse.de

ALTERNATING CURRENT CHARGING SYSTEMS

During cranking, the battery supplies all of the vehicle's electrical power. However, once the engine is running, the charging system is responsible for producing enough energy to meet the demands of all of the loads in the electrical system while also recharging the battery. With all of the electrical and electronic devices found on today's vehicles, the charging system has a difficult job.

Several decades ago the charging system depended on a **DC generator**. The DC generator provided direct current (DC) and was similar to an electric motor in construction. The biggest difference between a generator and a motor is the wiring to the armature. In a motor, the armature receives current from the battery. This creates the magnetic field that opposes the magnetic fields in the motor's coils, which causes the armature to rotate. The armature in a DC generator is driven by the engine. It is not magnetized and the windings simply rotate through the stationary magnetic field of the field windings, inducing a voltage in the conductors inside the armature. A motor can become a generator by allowing current to flow from the armature instead of to it. In a DC generator, the placement of the brushes on the commutator changes the induced AC voltage to a DC voltage output.

DC generators had a very limited current output, especially at low speeds. They could not keep up with demands of the modern automobile and were replaced by AC generators. AC generators are capable of providing high current output even at low engine speeds.

SHOP TALK

With the implementation of OBD II, new terminology was given to many parts of an automobile. Prior to that law, an AC generator was called an **alternator**. In fact, in many cases and by many manufacturers an AC generator is still referred to as an alternator. To avoid confusion, just remember that an alternator is an AC generator and vice versa.

AC generators use a design that is basically the reverse of a DC generator. In an AC generator (**Figure 19-3**), a spinning magnetic field (called the rotor)

Figure 19-3 A simplified AC generator.

Figure 19-4 The rotor is made up of a coil, pole pieces, and a shaft.

rotates inside an assembly of stationary conductors (called the stator). As the spinning north and south poles of the magnetic field pass the conductors, they induce a voltage that first flows in one direction and then in the opposite direction (AC voltage). Because automobiles use DC voltage, the AC must be changed or rectified into DC. This is done through an arrangement of diodes that are placed between the output of the windings and the output of the AC generator.

AC Generator Construction

Rotor The rotor assembly consists of a drive shaft, coil, and two pole pieces (**Figure 19-4**). A pulley mounted on one end of the shaft allows the rotor to be spun by a belt driven by the crankshaft pulley.

The **rotor** is a rotating magnetic field inside the alternator. The field coil is simply a long length of insulated wire wrapped around an iron core. The core is located between the two sets of **pole pieces**. A magnetic field is formed by a small amount (4.0 to 6.5 amperes) of current passing through the coil winding. As current flows through the coil, the core is magnetized and the pole pieces assume the magnetic polarity of the end of the core that they touch. Thus, one pole piece has a north polarity and the other has a south polarity. The extensions of the pole pieces, known as **fingers**, form the actual magnetic poles. A typical rotor has fourteen poles, seven north and seven south, with the magnetic field between the pole pieces moving from the N poles to the adjacent S poles (**Figure 19-5**).

Slip Rings and Brushes Current to create the magnetic field is supplied to the coil from one of two sources: the battery or the AC generator itself. In either case, the current is passed through the AC generator's voltage regulator before it is applied to the coil. The voltage regulator varies the amount of current supplied. Increasing field current through the coil increases the strength of the magnetic field. This, in

Figure 19-5 The magnetic field moves from the N poles, or fingers, to the S poles.

turn, increases AC generator voltage output. Decreasing the field current to the coil has the opposite effect. Output voltage decreases.

Slip rings and brushes (**Figure 19-6**) conduct current to the spinning rotor. Most AC generators have two slip rings mounted directly on the rotor shaft. They are insulated from the shaft and each other. Each end of the **field coil** connects to one of the slip rings. A carbon brush located on each slip ring carries the current to the field coil. Current is transmitted from the field terminal of the voltage regulator through the first brush and slip ring to the field coil. Current passes through the field coil and the second slip ring and brush before returning to ground (**Figure 19-7**).

Stator The **stator** is the stationary member of the generator. It is made up of a number of conductors,

Figure 19-6 The brushes ride on the slip rings.

Figure 19-7 Current is carried by the brushes to the rotor windings via the slip rings.

or wires, into which the voltage is induced. Most AC generators use three windings to generate the required amperage output. They can be arranged in either a **delta** configuration or a **wye** configuration (**Figure 19-8**). The delta winding (**Figure 19-9**) received its name because its shape resembles the Greek letter delta, Δ . The wye winding resembles the letter Y. Alternators use one or the other. Usually, a wye winding is used in applications in which high charging voltage at low engine speeds is required. AC generators with delta windings are capable of putting out higher amperages at high speeds but low engine speed output is poor.

The rotor rotates inside the stator. A small air gap between the two allows the rotor to turn without making contact with the stator.

Alternating current produces positive and negative pulses. The resultant waveform is a sine wave, which can be observed on a scope. The waveform starts at zero, goes positive, and then drops back to zero before turning negative. When the north pole magnetic field cuts across the stator, a positive voltage is generated. When the south polarity magnetic field cuts across the stator, a negative voltage is induced. A single loop of wire energized by a single north then a south result in a single-phase voltage. Remember that there are three overlapping stator windings. This produces overlapping sine waves (**Figure 19-10**) or **three-phase voltage**.

End Frame Assembly The end frame assembly, or housing, contains the bearings for the rotor shaft. Each end frame also has built-in ducts so the air from the rotor shaft fan can pass through the AC generator. Normally, a heat sink containing three positive rectifier diodes is attached to the rear end frame. Heat

Figure 19-8 A wye-connected stator winding.

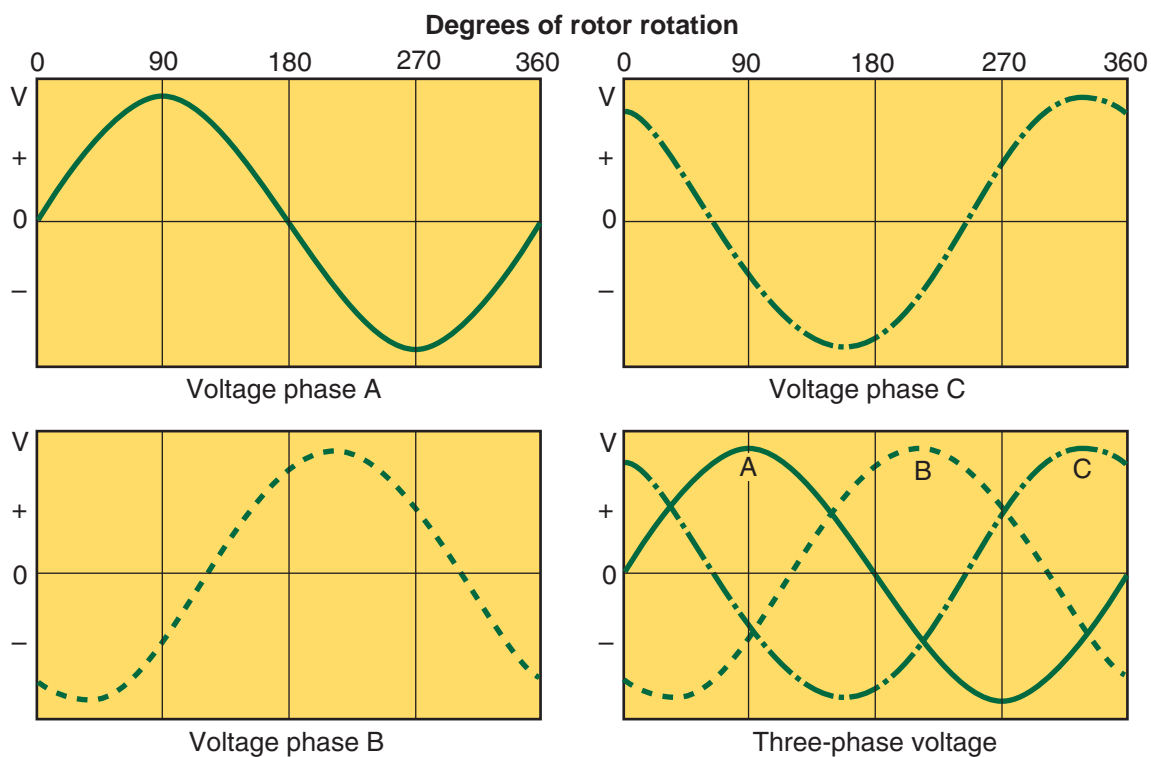

Figure 19-10 The voltage produced in each stator winding is added together to create a three-phase voltage.

Figure 19-11 A bridge rectifier mounted in the end frame.

can pass easily from these diodes to the moving air (**Figure 19-11**). Three negative rectifier diodes are contained in the end frame itself. Because the end frames are bolted together and then bolted directly to the engine, the end frame assembly is part of the electrical ground path. This means that anything connected to the housing that is not insulated from the housing is grounded.

Cooling Fans Behind the drive pulley on most AC generators is a cooling fan that rotates with the rotor. This cooling fan draws air into the housing through the openings at the rear of the housing. The air leaves through openings behind the cooling fan (**Figure 19-12**). The moving air pulls heat from the diodes and their heat decreases.

Figure 19-12 The cooling fan draws air in from the rear of the generator to keep the diodes cool. *Courtesy of Robert Bosch GmbH, www.bosch-presse.de*

Figure 19-13 A water-cooled AC generator. *Courtesy of BMW of North America, LLC*

Cooling the diodes is important for the efficiency and durability of an AC generator. Several generator designs have been introduced recently that increase the cooling efficiency of a generator. One of these is the AD-series generator from General Motors. The “A” stands for air cooled and the “D” means dual fans. This series is lighter than most other generators but capable of very high outputs. This type of generator does not have an external fan; instead, it has two internal fans.

Liquid-Cooled Generators Another recent design uses liquid cooling (**Figure 19-13**). Using water or coolant to cool a generator is a very efficient way to keep diode temperatures down. But the real reason for eliminating the fan and using liquid to cool the generator is to reduce noise. The rotating fan is a source of underhood noise that some automobile manufacturers want to eliminate. These new generators have water jackets cast into the housing. Hoses connect the housing to the engine’s cooling system. Not only do these generators make less noise, they have higher power output and should last longer in the high-temperature environment of the engine compartment.

AC GENERATOR OPERATION

As mentioned earlier, AC generators produce alternating current that must be converted, or rectified, to DC. This is accomplished by passing the AC through diodes.

Diodes

A **diode** allows current to flow in one direction but not in the opposite direction. Therefore, it can function as a switch, acting as either conductor or insulator,

Figure 19-14 The schematic symbols for two common components of a generator and voltage regulator: a diode and a zener diode.

depending on the direction of current flow. In an AC generator, current is rectified (changed from AC to DC) through the use of diodes. The diodes are arranged so that current can leave the generator in one direction only (as DC).

A variation of the diode is the zener diode (**Figure 19-14**). This device functions like a standard diode until a certain voltage is reached. When the voltage level reaches this point, the zener diode allows current to flow in the reverse direction. Zener diodes are often used in electronic voltage regulators.

DC Rectification

Figure 19-15 shows that when AC passes through a diode, the negative pulses are blocked off to produce the scope pattern shown. If the diode is reversed, it blocks off current during the positive pulse and allows the negative pulse to flow (**Figure 19-16**). Because only half of the AC current pulses (either the positive or the negative) is able to pass, this is called **half-wave rectification**.

By adding more diodes to the circuit, more of the AC is rectified. When all of the AC is rectified, **full-wave rectification** occurs.

Full-wave rectification requires another circuit with similar characteristics. **Figure 19-17** shows a wye

Figure 19-15 Half-wave rectification, diode positively biased.

Figure 19-16 Half-wave rectification, diode negatively biased.

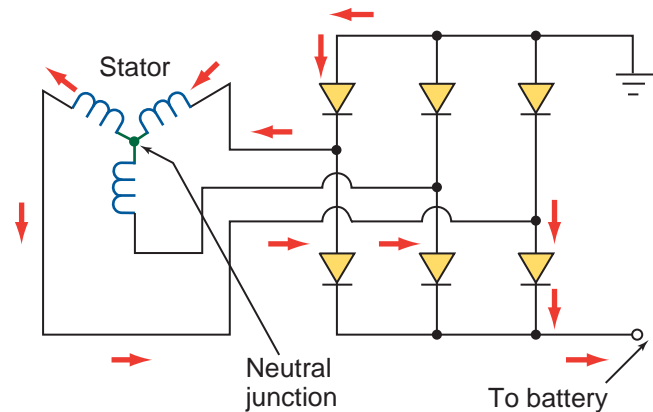

Figure 19-17 A wye stator wired to six diodes.

stator with two diodes attached to each winding. One diode is insulated, or positive, and the other is grounded, or negative. The center of the Y contains a common point for all windings. It can have a connection attached to it. It is called the stator neutral junction. At any time during the rotor movement, two windings are in series and the third coil is neutral and inactive. As the rotor revolves, it energizes the different sets of windings in different directions.

The diode action does not change when the stator and diodes are wired in a delta pattern. **Figure 19-18** shows the major difference. Instead of having two windings in series, the windings are in parallel. Thus, more current is available because the parallel paths allow more current to flow through the diodes. Nevertheless, the action of the diodes remains the same.

Many AC generators have an additional set of three diodes called the **diode trio**. The diode trio is used to rectify current from the stator so that it can be used to create the magnetic field in the rotor. Using the diode trio eliminates extra wiring. To control generator output, a voltage regulator regulates the current from the diode trio and to the rotor (**Figure 19-19**).

Figure 19-18 A delta stator wired to six diodes.

Figure 19-19 Wiring diagram of a charging circuit with a diode trio.

Factors Controlling Generator Output

Several factors determine the total output available from a generator other than the type of stator winding. These include:

- The rotational speed of the rotor. Higher speeds can lead to higher output.
- The number of windings in the rotor. Increased windings will increase output.
- The current flow through the rotor windings. Increased current through the rotor will increase output.
- The number of windings in the stator. An increase in the number of windings will increase output.

Often owners will change the size of the generator's pulley to decrease the drag on the

engine and, therefore, increase the engine's power output. Although the generator will spin at a lower speed, it also will have a lower output. Because the system will respond to the lower output by sending more current to the rotor, the magnetic field will be stronger and that alone will create more drag on the engine. Making the decision to change a generator pulley should be done only after much thought. If the battery is fully charged, there will be a net increase in engine output. If the battery is low on charge, there may be no gain at all.

VOLTAGE REGULATION

The output from an AC generator can reach as high as 250 volts if it is not controlled. The battery and the electrical system must be protected from this excessive voltage. Therefore, charging systems use a **voltage regulator** to control the generator's output. Voltage output is controlled by the voltage regulator as it varies the strength of the magnetic field in the rotor. Current output does not need to be controlled because an AC generator naturally limits the current output. To ensure that the battery stays fully charged, most regulators are set for a system voltage between 14.5 and 15.5 volts.

Voltage output is controlled by varying the field current through the rotor. The higher the field current, the higher the voltage output. By controlling the amount of resistance in series with the field coil, control of the field current and voltage output is obtained.

An input signal, called the **sensing voltage**, allows the regulator to monitor system voltage (**Figure 19-20**). If the sensing voltage is below the regulator setting, an increase in field current is allowed, which causes an increase in voltage output. Higher sensing voltage will result in a decrease in field current and voltage output. The regulator will reduce the charging voltage until it is at a level to run the ignition system while putting a low charge on the battery. If a heavy load is turned on, such as the headlights, the additional draw will cause a decrease in battery voltage. The regulator

Figure 19-20 The voltage regulator adjusts the generator's output according to the voltage on the sensing circuit.

will sense the low voltage and will increase current to the rotor. When the load is turned off, the regulator senses the rise in system voltage and reduces the field current.

Another input that affects voltage regulation is temperature. Because ambient temperature influences the rate of charge that a battery can accept, regulators are temperature compensated. Temperature compensation is required because the battery is more reluctant to accept a charge at lower ambient temperatures. The regulator will increase the voltage output to force a charge on the battery.

Field Circuits

A regulator controls field current and is connected in one of three ways to the rotor. These are called field circuits. The A-circuit has the regulator on the ground side of the field coil. The battery feed (B+) for the field coil is picked up inside the AC generator (**Figure 19-21**). By placing the regulator on the ground side of the field coil, the regulator controls

Figure 19-21 An A-circuit.

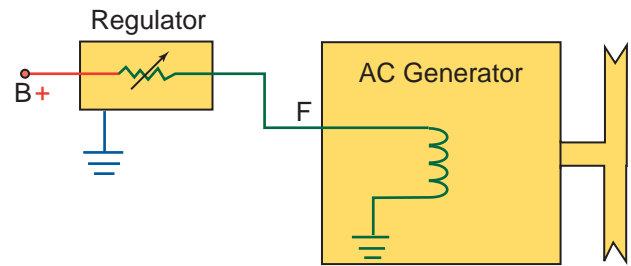

Figure 19-22 A B-circuit.

field current by varying the current flow to ground.

The second type of field circuit is the B-circuit. The voltage regulator controls the power side of the field circuit. The field coil is grounded inside the AC generator (**Figure 19-22**). Normally the B-circuit regulator is mounted outside the generator.

The third type of field circuit is called the isolated field. The AC generator has two field wires attached to the outside of the case. One wire is the ground; the other is the B+. The voltage regulator can be placed on either the ground or the B+ side of the circuit.

There are two basic types of regulators: electronic and electromechanical. Older vehicles were equipped with electromechanical regulators, whereas newer vehicles have an electronic regulator. Most newer vehicles do not have a separate voltage regulator; rather, they control charging system output through the PCM.

Electronic Regulators

Electronic regulators can be mounted outside the generator or be an integral part of the generator (**Figure 19-23**). Voltage output is controlled through the ground side of the field circuit (A-circuit control). Most electronic regulators have a zener diode that

Figure 19-23 An integrated voltage regulator.

Figure 19-24 A simplified circuit of an electronic regulator with a zener diode.

blocks current flow until a specific voltage is obtained, at which point it allows the current to flow. The schematic for an electronic voltage regulator with a zener diode is shown in **Figure 19-24**.

The generator's output is controlled by pulse width modulation. This varies the amount of time the field coil is energized in response to the vehicle's needs. For example, assume that a vehicle is equipped with a 100-ampere generator. If the electrical demand placed on the charging system requires 50 amps, the regulator would energize the field coil for 50% of the time. If the electrical system's demand were increased to 75 amps, the regulator would energize the field coil 75% of the cycle time.

Integrated circuit voltage regulators are used in many vehicles. These compact units are mounted either inside or on the back of the AC generator. Integrated circuit regulators are nonserviceable and must be replaced if defective.

The generator shown in **Figure 19-25** has an integrated regulator. The unit is mounted inside the generator's slip ring end frame along with the brush holder assembly. The regulator controls field current through a diode trio.

Fail-Safe Circuits To prevent simple electrical problems from causing high-voltage outputs that can damage delicate electronic components, many voltage regulators have **fail-safe circuits**.

If connections to the AC generator become corroded or accidentally disconnected, the regulator's fail-safe circuits may limit voltage output to prevent high-charging voltages. Under certain conditions, the fail-safe circuit may prevent the AC generator from charging at all. A fusible link or maxi-fuse in the fail-safe circuitry prevents high current from leaving the charging system and damaging the

Figure 19-25 Component locations of an AC generator with an internally mounted voltage regulator. Courtesy of Robert Bosch GmbH, www.bosch-presse.de

delicate electronic components in other vehicle systems.

Computer Regulation

Late-model vehicles do not have a separate voltage regulator. Instead voltage regulation is one of the many functions of the vehicle's PCM. The computer is used to control current to the field windings in the rotor.

This type of system switches or pulses field current on and off at a fixed frequency of about 400 cycles per second. A significant feature of this system is its ability to vary the amount of voltage according to vehicle requirements and ambient temperatures. This precise control allows the use of smaller, lighter storage batteries. It also reduces the magnetic drag of the AC generator, increasing engine output by several horsepower. Precise management of the charging rate also results in increased gas mileage.

The part of the PCM that controls charging output is typically called the power management system (**Figure 19-26**). This system not only controls the field current, it also causes the engine's idle speed to increase when the battery is low and sends diagnostic messages to alert the driver of possible battery and generator problems. The condition of the battery is monitored with the ignition off and when it is on.

When the ignition is off, the battery's state-of-charge (SOC) is monitored by open-circuit voltage. Engine-off SOC is used as an indicator of the battery's condition. When the engine is running, the system continuously estimates SOC based on temperature,

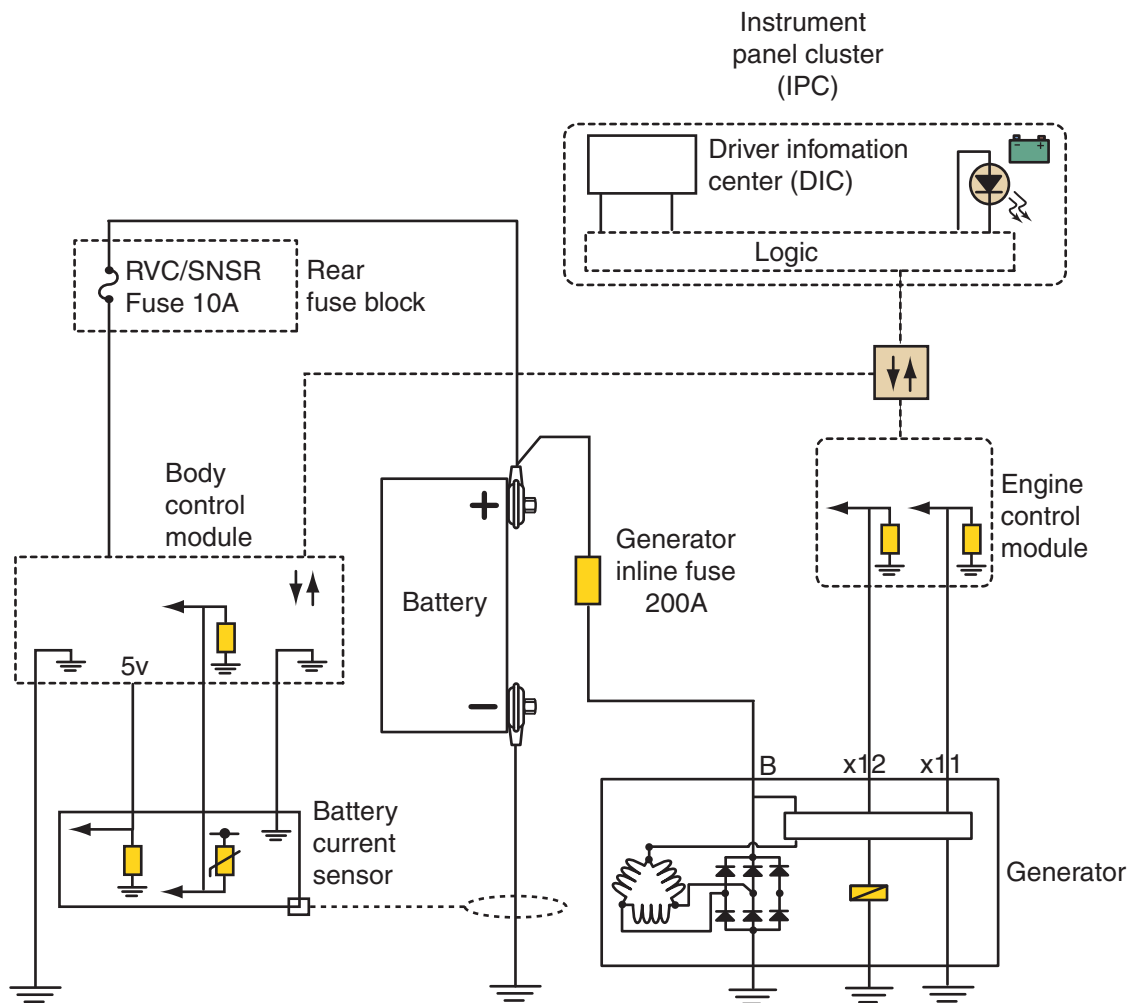

Figure 19-26 The main circuit for a PCM-controlled charging system.

battery capacity, the initial SOC, and the charging system's output.

NEW DEVELOPMENTS

In the quest to improve fuel economy, decrease emission levels, and make vehicles more reliable, engineers have applied advanced electronics to starters and generators.

Motor/Generators

Keep in mind that the main difference between a generator and a motor is that a motor has two magnetic fields that oppose each other, whereas a generator has one magnetic field and wires are moved through that field. Using electronics to control the current to and from the battery, a generator can also work as a motor. These units are called starter/generators or motor/generators. The construction of a motor/generator may be based on two sets of windings and brushes, a brushless design with a permanent magnet, or switched reluctance (**Figure 19-27**).

SHOP TALK

Although not commonly used today in automobiles, switched reluctance motors are common in other industries. Without going into great detail into their operation, the basics should be understood for the future. This design has a toothed stator and rotor and the rotor has no windings or magnets. The stator has slots containing a series of coil windings. A controller establishes a rotating magnetic field around the stator as it activates one coil set in the stator at one time. The timing of this activation is based on the position of the rotor. When one coil is energized, a magnetic field is formed around it. The rotor tooth that is closest to the magnetic field moves toward that field. When the tooth is close, current is switched to another stator winding and the tooth moves to it. As the current is sent to the consecutively placed windings, the rotor rotates.

Figure 19-27 A switched reluctance motor/generator. Note the design of the rotor. *Courtesy of Dana Corporation*

A motor/generator can be mounted externally to the engine and connected to the crankshaft by a drive belt. Belt-driven motor/generators have a belt tensioner that is mechanically or electrically controlled to allow it to drive or be driven by the engine's crankshaft. One system uses an electromagnetic clutch fitted to the crankshaft pulley. The clutch is engaged to allow the motor/generator to work as a generator or as a starter motor. When the engine is stopped, the crank pulley clutch disengages. Motor/generators can also be directly mounted to the crankshaft between the engine and transmission or integrated into the flywheel (**Figure 19-28**). The most common hybrid vehicles have two motor/generators: one that serves as the engine starting motor and a generator and the other as a traction motor and generator.

Figure 19-28 An integrated motor/generator assembly built into the flywheel. *Courtesy of BMW of North America, LLC*

Figure 19-29 Motor/generators are capable of high charging outputs and can crank the engine at high speeds. They also allow for stop-start, regenerative braking, and electrical assist. *Courtesy of Visteon Corporation™*

Motor/generators are capable of high charging outputs and can crank the engine at high speeds. They also allow for other features that make the vehicle more efficient (**Figure 19-29**):

- Stop-start
- Regenerative braking
- Electrical assist

CAUTION!

Always adhere to the precautions given by the manufacturer when working on or near high-voltage motor/generators and their related systems. Being careless can cause serious injuries, including death.

Regenerative Braking

When the brakes are applied in a conventional vehicle, friction at the wheel brakes converts the vehicle's kinetic energy into heat. With regenerative braking, that energy is used to recharge the batteries. The vehicle's kinetic energy is changed to electrical energy until the vehicle is stopped (**Figure 19-30**). At that point, there is no kinetic energy. Through electronic controls, the motor/generator functions as a generator. The rotor is driven by the engine, which is driven by the vehicle's wheels, as the vehicle is slowing down. The amount of energy captured by a regenerative braking depends on many things, such as the SOC of the battery and the speed at which the generator's rotor is spinning.

Figure 19-30 The power flow for a hybrid with two motor/generators during brake regeneration.

Regenerative braking not only recharges the battery pack, but the load of turning the generator's rotor helps slow and stop the vehicle. Regenerative braking is not used to completely stop the vehicle. A combination of conventional hydraulic brakes and regenerative braking is used. Hydraulic, friction-based brakes must be used when sudden and hard braking is needed. Regenerative braking systems are not a physical part of the brake system.

The system's controller regulates how fast the kinetic energy is converted, and thus regulates how fast braking will occur. The controller receives a signal from the brake pedal and other sensors. Based on programs, the controller determines the amount of regenerative and hydraulic braking needed. Regenerative braking works better when the generator's rotor spins fast. It works poorly at low speed; therefore, the controller must base the amount of regenerative braking on the vehicle's speed and the pressure applied to the brake pedal. The controller must also apply the regenerative braking smoothly so the vehicle does not jerk when it is engaged.

Regenerative braking is found on all hybrid vehicles. It can capture approximately 30% of the energy normally lost during braking in conventional vehicles. It is claimed that the electric energy resulting from regenerative braking supplies 20% of the energy used by a Toyota Prius. Regenerative braking also decreases brake wear and reduces maintenance costs.

42-Volt Generators

Nonhybrid vehicles equipped with a 42-volt electrical system will have an air- (Figure 19-31) or liquid-cooled generator capable of producing 42 volts and 5 to 10 kilowatts. Currently, a conventional 12-volt generator puts out about 1.5 kilowatts. Depending on

Figure 19-31 A belt-drive 42-volt motor/generator. Courtesy of Toyota Motor Sales, U.S.A., Inc.

the system, the vehicle may be fitted with a DC-to-DC converter that lowers some of the generator's high-voltage output to charge a 12-volt battery or power the vehicle's 12-volt loads (Figure 19-32). Some new generators use switched reluctance techniques. These generators are very efficient at low speeds.

PRELIMINARY CHECKS

The key to solving charging system problems is getting to the root of the trouble the first time. Once a customer drives away with the assurance that the problem is solved, another case of a dead battery is very costly—both in terms of a free service call and a damaged reputation. Add to this the many possible hours of labor trying to figure out why the initial repair failed, and the importance of a correct initial diagnosis becomes all too clear.

Figure 19-32 The different system layouts for 42-volt electrical systems: (A) a system with two batteries and a converter, (B) a system with one battery and a converter, (C) a two-battery system, and (D) a one-battery system.

Safety Precautions

- Disconnect the battery ground cable before removing any leads from the system. Do not reconnect the battery ground cable until all wiring connections have been made.
- Avoid contact with the AC generator output terminal. This terminal is hot (has voltage present) at all times when the battery cables are connected.
- The AC generator is not made to withstand a lot of force. Only the front housing is relatively strong.

When adjusting belt tension, apply pressure only to the front housing to avoid damaging the stator and rectifier.

- When installing a battery, be careful to observe the correct polarity. Reversing the cables destroys the diodes. Proper polarity must also be observed when connecting a booster battery, positive to positive and negative to ground.
- Keep the tester's carbon pile off at all times, except during actual test procedures.
- Make sure all hair, clothing, and jewelry are kept away from moving parts.

Indicators

Part of all charging circuits is some sort of charging system warning device or indicator. The sole purpose of these is to alert the driver when there is a problem. They are also one of the first things to check when a charging system problem is suspected. Vehicles have an ammeter, a voltmeter, an indicator light, and/or a message center in the instrument panel that allows the driver to monitor the charging system.

Indicator Light This is the simplest and most common method of monitoring charging system performance. When the system fails to supply sufficient current, the light turns on. However, when the ignition switch is first activated, the light also comes on. This is due to the fact that the AC generator is not providing power to the battery and other electrical circuits. Thus, the only current path is through the ignition switch, indicator light, voltage regulator, part of the AC generator, and ground, and then back through the battery (**Figure 19-33**). Once enough power is provided, the lamp should turn off.

If, when the engine is running, the electrical load is greater than what can be handled by the charging system, the indicator light should turn on. This occasionally happens when the engine is idling. If there are no problems, the light should go out as the engine speed is increased. If it does not, either the AC generator or regulator is not working properly. If the lamp does not light when the ignition is placed in the on position, check the bulb and its circuitry.

SHOP TALK

On some late-model cars, the indicator light may be combined with the oil pressure warning light and is usually labeled "engine." If this light turns on while the engine is running, either the AC generator is not charging or the oil pressure is low—or both.

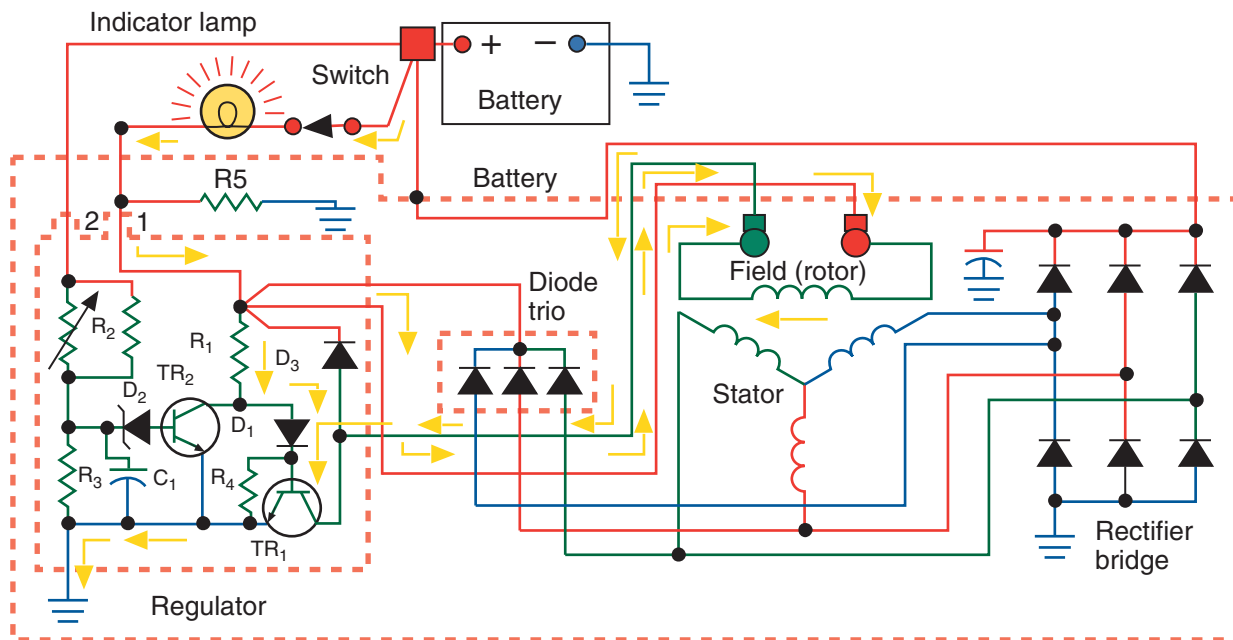

Figure 19-33 An electronic regulator with an indicator light “ON” due to no AC generator output.

Meters Some vehicles have an ammeter or voltmeter in their instrument cluster. The voltmeter displays the voltage at the battery. If the charging system is working fine, the voltmeter will read more than 12 volts. The ammeter monitors current flow in and out of the battery. When the generator is delivering current to the battery, the ammeter shows a positive (+) indication. When not enough current (or none at all) is being supplied, the result is a negative (–) indication. The latter situation indicates a problem with the charging system.

Warning Messages Warning messages are typically found on some vehicles with a PCM-controlled charging system. These messages are normally accompanied by the illumination of the charging system warning lamp. Like other warning lamp circuits, the lamp, along with a message, should be displayed when the ignition is first turned on. It should also turn off or clear once the engine is running, normally about 3 seconds. If the lamp and/or message remains on, the charging system needs to be diagnosed. If the lamp does not initially illuminate, that circuit needs to be diagnosed.

Normally the message center will display one of two messages when there is a faulty charging system. One message will say the battery is not being charged. An example for this would be: “Battery Not Charging Service Charging System.” If the system senses a too low or too high charging voltage, the typical message will read: “Service Battery Charging System.” Both of these messages will set a diagnostic trouble code that can be retrieved to help in diagnosis.

Inspection

Many charging system concerns are caused by easily repairable problems that reveal themselves during a visual inspection of the system. Remember to always look for the simple solution before performing more involved diagnostic procedures. Use the following inspection procedure when a problem is suspected.

PROCEDURE

Follow these steps while inspecting a charging system:

1. Inspect the battery. It might be necessary to charge the battery to restore it to a fully charged state. If the battery cannot be charged, it must be replaced. Also, make sure that the posts and cable clamps are clean and tight, because a bad connection can cause reduced current flow.
2. Inspect all system wiring and connections (**Figure 19-34**). Many systems contain fusible links or maxi-fuses to protect against overloads; check them.
3. Inspect the generator and regulator mountings for loose or missing bolts. Replace or tighten as needed. Remember, most generators and regulators complete their ground through their mounting. If the mountings are not clean and tight, a high resistant ground will result.
4. Inspect the AC generator drive belt. Loose drive belts are a major source of charging problems. The correct procedure for inspecting, removing, replacing, and adjusting a drive belt is shown in Photo Sequence 4.
5. Before adjusting belt tension, check for proper pulley alignment.

Figure 19-34 Start your diagnosis with an inspection of the generator and its drive belt and wires.

Chapter 7 for the procedures for checking and replacing drive belts and pulleys.

PCM-Controlled Systems

With PCM-controlled systems, diagnosis should continue with a check for diagnostic trouble codes (DTCs). Normally there are two possible types of charging system DTCs: generator related and battery current sensor related. Always refer to the manufacturer's DTC charts and follow its prescribed diagnostic steps for those codes. On most systems, the voltage output can be monitored with a scan tool. If the voltage is not within the range specified by the manufacturer, check all connections before continuing with other tests.

In a typical PCM-controlled charging system, the PCM controls the generator by controlling the duty cycle of the field current. The PCM will also change charging rates according to existing conditions (**Figure 19-35**). The PCM monitors a battery current sensor, the battery voltage, and the estimated battery temperature to determine the battery's SOC. The PCM can also increase the idle speed of the engine to raise charging rates in order to meet the current needs. The PCM sets a target charging output and adjusts the duty cycle of the field current to meet that target (**Table 19-1**) without overstressing the battery.

The battery current sensor is connected to the negative battery cable at the battery. The current sensor is a three-wire, Hall-effect sensor that

directly feeds the PCM with information. The actual voltage regulator may be connected internally to the generator but it is controlled externally by the PCM. If the voltage regulator detects a charging system problem, it grounds the sensor's circuit, which signals the PCM that a problem exists. The PCM then controls the duty cycle based on information in its memory.

Several conditions will cause the PCM to increase or decrease the target charging output. These include the current operation of some heavy current draw accessories, low current demand at constant vehicle speeds, low speed after initial engine startup, and low or high temperatures. When monitoring the performance of these systems, it is important to note the operational conditions because these do affect the output of the generator.

At times it may be necessary to reprogram the computer with newer software. When doing this, always follow the instructions given by the manufacturer.

Chapter 22 for a discussion and typical procedures for reprogramming a vehicle's computer.

Noise Diagnosis

Often a charging system concern is excessive noise. The cause of this noise can be something mechanical or electrical. Most often, electrical noise is normal and will vary with the load put on the charging system. However, a bad diode can cause an abnormal whirring noise and should be considered.

Most noises are caused by belts, bad bearings, or something rubbing against a pulley or belt. As with all problems, verify the noise and attempt to identify the area it is coming from. If a drive belt does not have the proper tension, it might produce a loud squealing sound. Check the condition and tension of the belt.

Check the mounting of the generator, its wiring harness, and all heater hoses, A/C lines, and other items that may be misrouted and making contact with belts or pulleys. If the cause of the noise is not identified, remove the drive belt. Spin the generator's pulley, idler pulley, and tensioner. If any of these do not spin freely, replace them. If no problem is found, check the tightness of the generator's mounting bolts and make sure the generator is

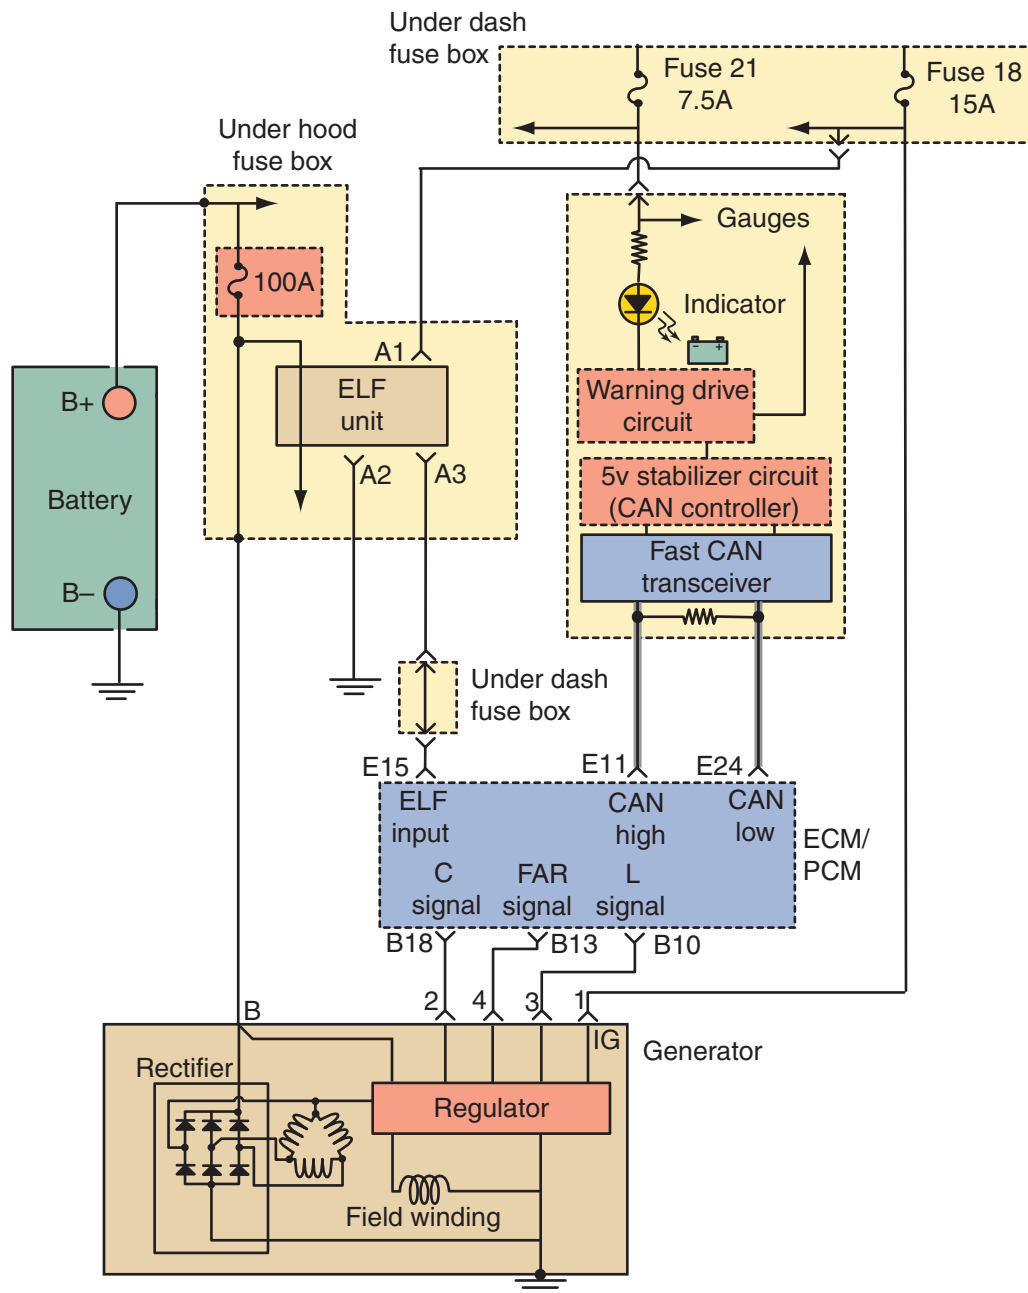

Figure 19-35 A schematic for a PCM-controlled charging system.

mounted correctly. If no problem is found, replace the generator.

GENERAL TESTING PROCEDURES

Diagnosing a charging system is a straightforward task. Tests can be conducted with a VAT, current probe, DMM, or a lab scope. Charging system tests for all cars are basically the same; however, it is very important to refer to the manufacturer's specifications. Even the most accurate test results are no good if they are not matched against the correct specs.

Regulator Tests

If the concern is excessive charge resulting in battery or component failure, the most likely cause is the voltage regulator. Seldom does a bad regulator cause low output, but it can cause no output. To determine if the regulator was the cause on older generators, the regulator was bypassed or full-fielded. This is not done with today's generators.

This requires knowledge of the type of field circuit the generator has. Then the field windings are given full current and the generator's output observed. Some generators had a window with a grounding tab

TABLE 19-1 THE RELATIONSHIP BETWEEN THE CONTROLLED OR COMMANDED FIELD CIRCUIT CURRENT DUTY CYCLE AND THE VOLTAGE OUTPUT OF THE GENERATOR

Commanded Duty Cycle	Output Voltage
10%	11 V
20%	11.6 V
30%	12.1 V
40%	12.7 V
50%	13.3 V
60%	13.8 V
70%	14.4 V
80%	15 V
90%	15.5 V

inside. By inserting a small screwdriver into the hole and grounding the tab, the regulator was bypassed. Also follow the manufacturer's procedures for full-fielding a generator.

Voltage Output Test

To check the charging system's voltage output, begin by measuring the battery's open circuit voltage. If the voltage is low, proceed to check the battery's condition. Then, start the engine and run it at the suggested rpm for this test (usually 1,500 rpm). With no electrical load, the voltage reading should be about 2 volts higher than the open circuit voltage.

A reading of less than 13 volts immediately after starting the engine indicates a charging problem. A reading of 16 or more volts indicates overcharging. A faulty voltage regulator or control voltage circuit is the most likely cause of overcharging.

If the unloaded charging system voltage is within specifications, test the output under a load. Increase the engine speed to about 2,000 rpm and turn on the headlights and other high current accessories. The voltage output while under heavy load should be about 0.5 volt above the battery's open circuit voltage.

Current Output Test

The output test looks at the current output of the system. A VAT can quickly check the amperage output. With the tester connected to the system (**Figure 19-36**), the engine is run at a moderate speed (2,500 rpm) and the carbon pile adjusted to obtain maximum current output. This reading is compared

Figure 19-36 The lead connections for conducting a current output test with a VAT. Notice that the ammeter clamp is around the battery cable. *Courtesy of Chrysler LLC*

against the rated output. Normally, readings that are more than 10 amperes out of specifications indicate a problem and the generator should be repaired or replaced.

SHOP TALK

It is important to know the amperage rating of the generator before coming to any conclusions from the output test. The generator may have its rating stamped into its case, there may be a label on the case, and some have color markings that denote their rating. However, the appropriate service manual is the best way to identify the rating.

AC Leakage Test

It is important to remember that a battery cannot be charged with AC voltage. Therefore, it is important to make sure that no AC is leaking into the charging system from the AC generator. Leakage typically occurs at a faulty diode. To check for diode leakage, connect a DMM in series to the generator's output terminal while the engine is not running (**Figure 19-37**). Set the meter to read milliamps. There should be no more than 0.5 milliamp. If there is more, check the diodes and/or replace the generator.

Diode Checks

The output of a generator is highly dependent on the condition of the diodes. Not only do the diodes rectify AC voltage to DC, they also prevent AC voltage from being present in the output. Bad diodes are indicated by the presence of more than 0.5 AC volt in the output wire. To check this, set the DMM to measure AC volts. Then connect the black meter lead to a

Figure 19-37 Setup for checking AC leakage.

good ground and the red lead to the generator's battery terminal.

Another check of the diodes while they are still in the generator is done with the engine off and with a low-amperage current probe. Measure the current on the generator's output wire. Any measurement greater than 0.5 milliamp indicates that one or more diodes are leaking and the generator or diodes need to be replaced.

Oscilloscope Checks

AC generator output can also be checked using an oscilloscope. **Figure 19-38** illustrates common AC generator voltage patterns for good and faulty generators. The correct pattern looks like the rounded top of a picket fence. A regular dip in the pattern indicates that one or more of the coil windings is grounded or open, or that a diode in the rectifier circuit of a diode trio circuit has failed. One or more bad or leaking diodes will decrease the output of a generator.

Generator Output and Generator Voltage Drop Tests

These tests measure voltage drop within the system wiring. They help pinpoint corroded connections or loose or damaged wiring.

Circuit resistance is checked by connecting a voltmeter to the positive battery terminal and the output, or battery terminal of the AC generator. The positive lead of the meter should be connected to the AC generator output terminal and the negative lead to the positive battery terminal (**Figure 19-39**). To check the voltage drops across the ground circuit, connect the positive lead to the generator housing and the negative meter lead to the battery negative terminal. When measuring the voltage drop in these circuits, a sufficient amount of current must be flowing through the circuit. Therefore, turn on the headlights and other accessories to ensure that the AC generator is putting out at least 20 amps. If a voltage drop of more than 0.5 volt is measured in either circuit, there is a high-resistance problem in that circuit.

AC GENERATOR SERVICE

When the cause of charging system failure is the AC generator, it should be removed and replaced or rebuilt. Whether it is rebuilt or replaced depends on the type of generator it is, the time and cost required to rebuild it, your shop's policy, and your customer's desires. Most late-model AC generators are not rebuilt. They are traded in as a core toward the purchase of a new or remanufactured unit. Just in case you do need to rebuild one, Photo Sequence 17 is given as an example of what it takes to do so. This procedure is for a specific type and model of generator. Make sure you follow the procedures given by the manufacturer for the generator you are working on.

To test the components of an AC generator it must be removed and disassembled.

A faulty AC generator can be the result of many different types of internal problems. Diodes (**Figure 19-40**), stator windings (**Figure 19-41**), and field circuits (**Figure 19-42**) may be open, shorted (**Figure 19-43** and **Figure 19-44**), or improperly grounded. The brushes or slip rings can become worn. The rotor shaft can become bent and the pulley can work loose or bend out of proper alignment.

Follow service manual procedures when removing and installing an AC generator. Remember, improper connections to an AC generator can destroy it.

Follow service manual procedures for disassembling, inspecting, testing, and rebuilding AC generators.

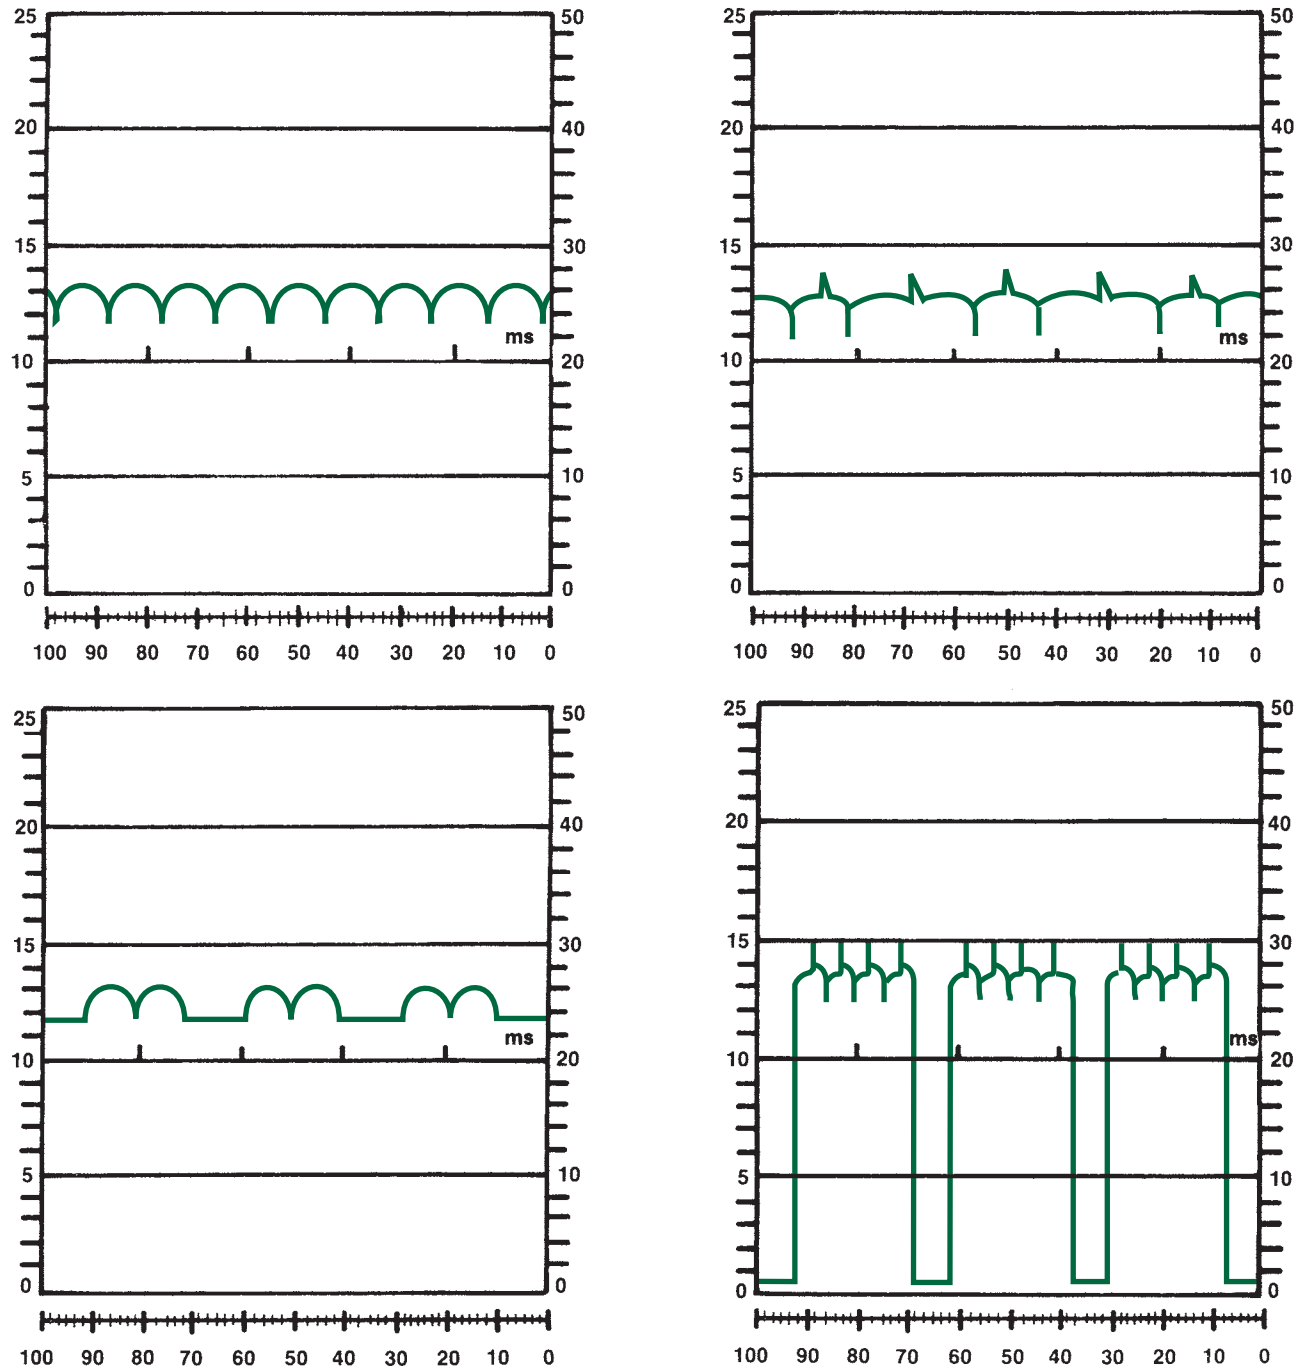

Figure 19-38 AC generator oscilloscope patterns: (A) good AC generator under full load, (B) good AC generator under no load, (C) shorted diode and/or stator winding under full load, and (D) open diode in diode trio.

Figure 19-39 Check the resistance of the charging circuit by measuring the voltage drop from the positive side of the battery to the output terminal of the generator. Remember, the system must be working and current flowing to measure voltage drop.

Figure 19-42 Testing a rotor for opens.

Figure 19-41 Testing a stator for opens.

Figure 19-44 Testing a rotor for a short to ground.

Typical Procedure for Disassembling a Ford IAR AC Generator

P17-1 Always have a clean and organized work area. The tools required to disassemble a Ford IAR AC generator are rags, T20 torx wrench, plastic hammer, arbor press, 100-watt soldering iron, soft-jawed vise, safety glasses, and an assortment of sockets or nut drivers.

P17-2 Using the torx wrench, remove the four attaching screws that hold the regulator to the AC generator housing.

P17-3 Remove the regulator and brush assembly as a unit.

P17-4 Using the torx wrench, remove the two screws that attach the regulator to the brush holder. Then separate the regulator from the brush holder.

P17-5 Scribe or mark the two end housings and the stator core for reference during reassembly.

P17-6 Remove the three through-bolts that secure the two housings.

P17-7 Separate the front housing from the rear housing. The rotor will come out with the front housing, and the stator will stay in the rear housing. It may be necessary to tap the front housing with the plastic hammer to get the two halves to separate.

P17-8 Separate the three stator lead terminals from the rectifier bridge.

P17-9 Remove the stator coil from the housing.

Typical Procedure for Disassembling a Ford IAR AC Generator *(continued)*

P17-10 Using the torx wrench, remove the four attaching bolts that hold the rectifier bridge.

P17-11 Remove the rectifier bridge from the housing.

P17-12 Use a socket or a bearing driver to tap out the bearing from the housing.

P17-13 Clamp the rotor in the vise.

P17-14 Remove the pulley-attaching nut, flat washer, drive pulley, fan, and fan spacer from the rotor shaft.

P17-15 Separate the front housing from the rotor. If the stop ring is damaged, remove it from the rotor. If not, leave it on the shaft.

P17-16 Remove the three screws that hold the bearing retainer to the front housing.

P17-17 Remove the bearing retainer.

P17-18 Remove the front bearing from the housing. Test and inspect all parts. Replace any defective ones. Reassembly is the reverse of this procedure.

CASE STUDY

A customer brought his pickup truck into the dealership with a complaint that the truck must be jumped to get it started and once it is started, it runs for about 10 minutes then dies.

The technician verified the complaint, then did a visual inspection of the charging system. Based on the complaint, he knew that the battery was not being kept in charge by the AC generator or that the battery was unable to hold a charge. He found the drive belt extremely frayed and glazed. Knowing this could cause the problem, he replaced the belt. However, before releasing the truck back to the customer he tested the battery to make sure it was able to hold a charge if the AC generator was capable of charging it. The battery checked out fine. He then checked the AC generator output and found it to be within specifications. This was a capable technician; he knew that he should not assume that the obvious problem was the only problem. As a result, the customer was happy and should be for quite some time.

SUMMARY

- Inducing a voltage requires a magnetic field producing lines of force, conductors that can be moved, and movement between the conductors and the magnetic field so the lines of force are cut.
- Modern vehicles use an AC generator to produce electrical current in the charging system. Diodes in the generator change or rectify the alternating current to direct current.

- A voltage regulator keeps charging system voltage above battery voltage. Keeping the AC generator charging voltage above the 12.6 volts of the battery ensures that current flows into, not out of, the battery.
- Modern voltage regulators are completely solid-state devices that can be an integral part of the AC generator or mounted to the back of the generator housing. In some vehicles, voltage regulation is the job of the computer control module.
- Voltage regulators work by controlling current flow to the AC generator field circuit. This varies the strength of the magnetic field, which in turn varies current output.
- The driver can monitor charging system operation with indicator lights, a voltmeter, or an ammeter.
- Using electronics to control the current to and from battery, a generator can work as a motor or vice versa.
- Motor/generators are capable of high charging outputs. They can crank the engine at high speeds and allow for the stop-start feature and regenerative braking and may provide electrical assist to the engine.
- Regenerative braking captures some of the vehicle's kinetic energy to recharge the battery.
- Problems in the charging system can be as simple as worn or loose belts, faulty connections, or battery problems.
- Circuit resistance, current output, voltage output, field-current draw, and voltage regulator tests are all used to troubleshoot AC charging systems.

REVIEW QUESTIONS

1. *True or False?* A faulty voltage regulator can cause a no-charge or overcharge condition.
2. To protect electronic circuits, some voltage regulators have a _____ circuit built into them.
3. What is the purpose of a rectifier assembly?
4. How does a voltage regulator regulate the voltage output of an AC generator?
5. What are the four factors that determine how much voltage is induced by a magnet?
6. What would happen to the output of an AC generator if one of the stator windings has an open?
7. Describe the basic difference between a DC motor and a DC generator.

ASE-STYLE REVIEW QUESTIONS

8. A rotating magnetic field inside a set of conducting wires is a simple description of a _____.
 - a. DC generator
 - b. AC generator
 - c. voltage regulator
 - d. none of the above
9. *True or False?* If the generator's voltage is within specifications, the generator is operating properly.
10. What part of the AC generator is the rotating magnetic field?
 - a. stator
 - b. rotor
 - c. brushes
 - d. poles
11. Which type of stator winding produces higher AC generator output at low speeds?
 - a. wye
 - b. delta
 - c. trio
 - d. series
12. Slip rings and brushes _____.
 - a. mount on the rotor shaft
 - b. conduct current to the rotor field coils
 - c. are insulated from each other and the rotor shaft
 - d. all of the above
13. The alternating current produced by the AC generator is rectified into DC, or direct current, through the use of _____.
 - a. transistors
 - b. electromagnetic relays
 - c. diodes
 - d. capacitors
14. A voltage drop over _____ indicates high resistance in either the positive or ground circuit of the charging system.
 - a. 0.1
 - b. 0.2
 - c. 0.5
 - d. 1.0
15. Voltage regulation by a PCM is done by _____.
 - a. using a variable resistor to vary current flow to the rotor field windings
 - b. pulsing current flow to the rotor field windings on and off to create a correct average field current supply
 - c. changing the duty cycle of a current sensor to control the field's path to ground
 - d. none of the above

1. Technician A says that the waveform produced by an AC generator before rectification is called a sine wave. Technician B says that the waveform produced by the AC generator after the output moves through the diodes is a straight line because it is a constant DC voltage. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
2. While discussing what is indicated by a vehicle's charge indicator: Technician A says that any positive reading on an ammeter shows that the battery is in good condition. Technician B says that if the voltmeter reading does not increase immediately after starting the engine, the battery is bad. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
3. When checking the charging system on a late-model vehicle: Technician A connects a scan tool to monitor the system's voltage output. Technician B connects a scan tool to retrieve any DTCs that may be in the system. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
4. While diagnosing the cause of a noise coming from a generator: Technician A says that the noise can be caused by something mechanical or electrical. Technician B says that the whirring noise is probably caused by a diode and it should be considered normal. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
5. Technician A uses a current output test to check AC generator output. Technician B uses a voltage output test to check output. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
6. Technician A says that many newer charging systems do not have a separate voltage regulator. Technician B says that most late-model charging systems are wired as A-type circuits and that the voltage is regulated through the ground of the field. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B

7. While diagnosing the braking system on a hybrid vehicle: Technician A says that the difficulty of the vehicle to come to a quick stop can be caused by the regenerative braking system. Technician B says that the difficulty of the vehicle to come to a quick stop can be caused by the hydraulic braking system. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
8. Technician A says that if there was no output from the charging system until the AC generator was full-fielded, the voltage regulator is faulty. Technician B says that this indicates one or more leaking diodes in the generator. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
9. When checking AC generator output on a late-model vehicle: Technician A tests the battery's open circuit voltage before testing the generator's output because the battery's SOC will affect the maximum output of the generator. Technician B checks the ambient temperature before performing any tests because the generator's output will be affected by temperature. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B
10. While testing a charging system: Technician A says that an overcharge condition is evident any time charging voltage is greater than 13 volts. Technician B says that the system should be able to supply its maximum current output when the engine is at idle and there is no load on the system. Who is correct?
 - a. Technician A
 - b. Technician B
 - c. Both A and B
 - d. Neither A nor B

LIGHTING SYSTEMS

OBJECTIVES

- Explain the operating principles of the various lighting systems. ■ Describe the different types of headlights and how they are controlled. ■ Understand the functions of turn, stop, and hazard warning lights. ■ Know how back-up lights operate. ■ Replace headlights and other burned-out bulbs. ■ Explain how to aim headlights. ■ Explain the purpose of auxiliary automotive lighting. ■ Describe the operation and construction of the various automotive lamps. ■ Diagnose lighting problems.

The lighting system provides power to both exterior and interior lights. It consists of the headlights, parking lights, marker lights, taillights, courtesy lights, dome/map lights, instrument illumination or dash lights, coach lights (if so equipped), headlight switch, and various other control switches (**Figure 20-1**). Other lights, such as vanity mirror lights, the underhood light, the glove box light, and the trunk compartment light, are used on some vehicles and are also part of the lighting system.

Other lights that are not usually in the main lighting system are turn signal, hazard warning, back-up,

and stoplights. These lights, as well as the pop-up headlights or retractable headlight covers found on some vehicles, are operated by separate control circuits and are covered later in this chapter.

SHOP TALK

Lighting systems are largely regulated by federal laws, so the systems are similar among the various manufacturers. However, there are many variations. Before attempting to do any repairs on an unfamiliar system, you should always refer to the manufacturer's service manual.

Figure 20-1 Automotive lighting systems.

LAMPS

A **lamp** generates light as current flows through the filament. This causes it to get very hot. The changing of electrical energy to heat energy in the resistive wire filament is so intense that the filament starts to glow and emits light. The glass envelope that encloses the filament is evacuated so that the filament “burns” in a vacuum. If air enters the envelope, the oxygen would cause the filament to oxidize and burn up.

It is important that any burned-out lamp be replaced with the correct lamp. You can determine what lamp to use by checking the lamp's standard trade number, usually present on the lamp's housing. Lamps are normally one of two types: a single filament (**Figure 20-2**) or a double filament (**Figure 20-3**). Double-filament bulbs are designed to

Figure 20-2 A single-filament bulb.

Figure 20-3 A double-filament bulb.

serve more than one function. They can be used as the lone bulb in the stoplight circuit, taillight circuit, and the turn signal circuit.

HEADLIGHTS

Headlights are mounted on the front of a vehicle to light the road ahead during darkness or other times when normal visibility is poor. Headlight designs and construction have been influenced by the changes in technology. In the past, all cars had two or four round or rectangular headlights. Now headlights are an integral part of a vehicle's overall design (Figure 20-4).

Sealed-Beam Headlights

Until recently, all vehicles had sealed-beam headlights. A **sealed-beam** headlamp is an air-tight

Figure 20-4 Today's headlights are an integral part of the appearance of vehicles.

assembly with a filament, reflector, and lens. The curved reflector is sprayed with vaporized aluminum and the inside of the lamp is normally filled with argon gas. The reflector intensifies the light produced by the filament, and the lens directs the light to form a broad flat beam (Figure 20-5). To direct the light, the surface of the glass lens has concave prisms.

Low- and high-beam filaments are placed at slightly different locations within a sealed-beam bulb (Figure 20-6). The filaments' location determines how light passes through the bulb's lens. This, in turn, determines the direction of the light beam. In a dual-filament lamp, the lower filament is used for the high beam and the upper filament is used for the low beam.

There are various ways to identify sealed-beam headlights, such as #1, #2, and the "halogen" or "H" marking molded on the front of the headlight lens. A type #1 is high beam only and has two electrical terminals. The type #2 has both low beam and high beam and three terminals. When a type #2 is switched to low beam, only one of its filaments is lit. When the

Figure 20-5 The reflector intensifies the light produced by the filament, and the lens directs the light to form a broad flat beam.

Figure 20-6 Filament placement controls the projection of the light beam.

high beam is selected, the second filament lights in addition to the low beam.

When there are four headlights (two on each side), the single filament of the #1 lamp lights when the high beam is selected, along with both filaments of the #2 bulb. H1 and H2 quartz halogen bulbs are the most commonly used sealed-beam headlights.

Halogen Lamps The most commonly used sealed-beam headlight is the halogen type (**Figure 20-7**). **Halogen** is a term used to identify a group of chemically related nonmetallic elements. These elements include chlorine, fluorine, and iodine. Most often a halogen headlamp is filled with iodine vapor. This headlamp is actually a bulb made of high-temperature resistant glass surrounding a tungsten filament. The bulb is inserted into a sealed glass or plastic housing. The tungsten filament is capable of withstanding higher temperatures than that of standard sealed-beam lamps because of the presence of the halogen. Therefore, because it can withstand higher temperatures, it can burn brighter.

Figure 20-7 A sealed-beam halogen headlamp.

Figure 20-8 A composite headlamp with a replaceable halogen bulb.

SHOP TALK

Because the filament is inside the inner bulb, cracking or breaking of the housing or lens does not prevent a halogen bulb from working. As long as the filament envelope has not been broken, the filament will continue to operate. However, a broken lens will result in poor light quality, so the lamp assembly should be replaced.

Composite Headlights

Many of today's vehicles have halogen headlight systems that use a replaceable bulb (**Figure 20-8**). These are called **composite headlights**. By using these, manufacturers are able to produce any style of headlight lens they desire. This improves the aerodynamics, fuel economy, and styling of the vehicle.

Composite headlight housings are often vented to release some of the heat developed by the bulbs. The vents allow condensation to collect on the inside of the lens assembly. The condensation is not a problem and does not affect headlight operation. When the headlights are turned on, the heat generated by the halogen bulb quickly dissipates the condensation. Ford uses integrated nonvented composite headlights. On these vehicles, condensation is not considered normal. The assembly should be replaced.

WARNING!

Whenever you replace a composite lamp, be careful not to touch the lamp's envelope with your fingers. Staining the bulb with skin oil can substantially shorten the life of the bulb. Handle the bulb only by its base.

Figure 20-9 A headlamp assembly with cylindrical bulb housings.

Cylindrical Housings To provide more precise light beam patterns, many manufacturers are using headlamp assemblies that have cylindrical bulb housings (**Figure 20-9**). The light beam is shot out of the cylinder. The aim of the cylinder projects the beam without much scattering.

HID Headlamps

High-intensity discharge (HID) or xenon headlamps use gas-discharge lamps and are electronically controlled. These lights are recognizable by the blue-white color of their light (**Figure 20-10**). They have this color because the light's spectrum is much closer to daylight than that of a halogen bulb.

Instead of using a filament, an electrical arc is created between two electrodes that excite a gas (usually xenon) inside the headlamp (**Figure 20-11**), which in turn vaporizes metallic salts that sustain the arc and emit light. The presence of an inert gas amplifies the light given off by this arcing.

Figure 20-10 HID (xenon) headlights are readily identifiable by their bluish light. *Courtesy of Chrysler LLC*

Figure 20-11 A xenon light bulb. *Courtesy of Chrysler LLC*

More than 15,000 volts are used to jump the gap between the electrodes. To provide this voltage, a voltage booster and controller is required. Once the high voltage bridges the gap, only about 80 volts are needed to keep current flowing across the gap. When the headlights are switched on, it takes approximately 15 seconds for the lamps to reach maximum intensity. However, even during ignition these lamps provide more than adequate light for safe driving.

Xenon headlamps illuminate the area to the front and sides of the vehicle with a beam that is both brighter and much more consistent than the light generated by halogen headlamps. The great light output of these lamps allows the headlamp assembly to be smaller and lighter. Xenon lights also produce significantly less heat.

Xenon headlights produce about twice as much light as comparable halogen headlights (**Figure 20-12**) and make night driving safer and less tiring for the driver's eyes. Xenon headlamps also use about two-thirds less power to operate and will last two or three times as long.

Bi-Xenon Lights Some vehicles have bi-xenon headlamps that provide xenon lights for low and high beams. These may also be fitted with halogen lights that are used for the flash-to-pass feature. Bi-xenon lights rely on a mechanical shield plate, or shutter, that physically obstructs a portion of the overall light beam emitted by the arc. When the driver selects high beams, the shutter reacts and allows the headlights to project the complete, unobstructed light beam.

SHOP TALK

HID lamps offer great visibility but often drivers approaching a vehicle with HID headlamps become annoyed by the glare or brightness of the lamps. To eliminate these concerns, HID systems often have self-leveling and washer systems. Both of these are required in Europe and most European vehicles with HID headlamps have these features.

LED Headlights

Currently under development and perhaps available on some vehicles at this time are LED headlamps. **Light-emitting diodes (LEDs)** are semiconductors that change electrical energy into light. LEDs are used in many other systems and those are discussed later in this chapter. An individual LED does not produce enough light to serve as a headlamp. Ten to twenty LEDs are needed for ample forward lighting (**Figure 20-13**). There are many reasons for using LEDs in headlamps:

- LEDs do not require a vacuum bulb or high voltage to work.
- LED-based lighting sources require up to 40% less power than traditional lighting sources. This improves a vehicle's fuel economy.
- LEDs provide a whiter light than xenon.

Figure 20-13 This headlight assembly combines a xenon bulb with LEDs. The number of LEDs that are energized depends on the driving conditions.

- Prototype LED headlamps have achieved a 1,000-lumen output in the low-beam mode; this is the same as a xenon headlamp.
- LEDs are mercury-free, making them environmentally friendly unlike some HID/xenon systems.
- The average operating life of an LED is twice that of the vehicle itself. This means the headlamp may never need to be replaced.
- LEDs are resistant to shock and vibration.
- LED headlamps reduce oncoming driver perception of glare.
- LED-based headlamps are up to 55% thinner than other designs, which gives designers more flexibility and freedom.

Incorporating LED technology into headlamps presents a problem common to all semiconductors, that being heat. The heat from the engine compartment and the lamp can cause failure. Therefore, LEDs need temperature controls and must be mounted to heat-retarding materials. LEDs also require precise current control, which requires complicated electronic circuitry. In spite of these obstacles, LED headlamps can open the door to other headlamp-related safety features. It is possible to have light beams that meet the current conditions automatically. This can be done by varying the number of LEDs powered or by the placement of special lenses in front of a particular group of LEDs. It is predicted that as LEDs become more powerful and less expensive, they may replace xenon headlamp systems.

Headlight Switches

Headlight switches are either mounted to the instrument panel (**Figure 20-14**) or are part of the multi-function switch on the steering column. The headlight

Figure 20-14 A headlight switch that also has positions for rear and front fog lights.

switch controls most of the exterior lighting for the vehicle. Most switches have three positions: off, park, and headlight. Most vehicles have a warning system that alerts the driver that the park or headlamps are on and that the driver's door is open.

When the headlight switch is in the OFF position, the open contacts prevent battery voltage from continuing on to the lamps (**Figure 20-15**). When the switch is in the PARK position, battery voltage is applied to the parking lights, side markers, taillights, license plate lights, and instrument panel lamps. This

circuit is usually protected by a 15- or 20-amp fuse that is separate from the headlight circuit.

When the switch is in the HEADLIGHT position, battery voltage is applied to the headlights. The lamps lit by the PARK position remain on. Normally, a self-resetting circuit breaker is installed between the battery feed and the headlights. The circuit breaker is designed to reset itself. If a problem causes the breaker to open, the lights will go off until the breaker resets. Then the lights will come back on. If there is a serious problem in the circuit, the headlights might flash as the breaker cycles. Some vehicles have a separate fuse for the headlight on each side of the vehicle. This allows one headlight to operate if there is a problem in the circuit for one side of the vehicle.

The instrument panel lights come on whenever the headlight switch is in the PARK or HEADLIGHT position. The brightness of these lamps is adjustable. A rheostat is used to allow the driver to control the brightness of the bulbs. This control may be part of the headlight switch, in which case the driver simply rotates the headlight switch knob to adjust the panel lights. Most vehicles have a separate control for instrument panel brightness (**Figure 20-16**). Some of these display a brightness scale on the instrument panel (**Figure 20-17**) to show the driver where the lights are adjusted within their possible range.

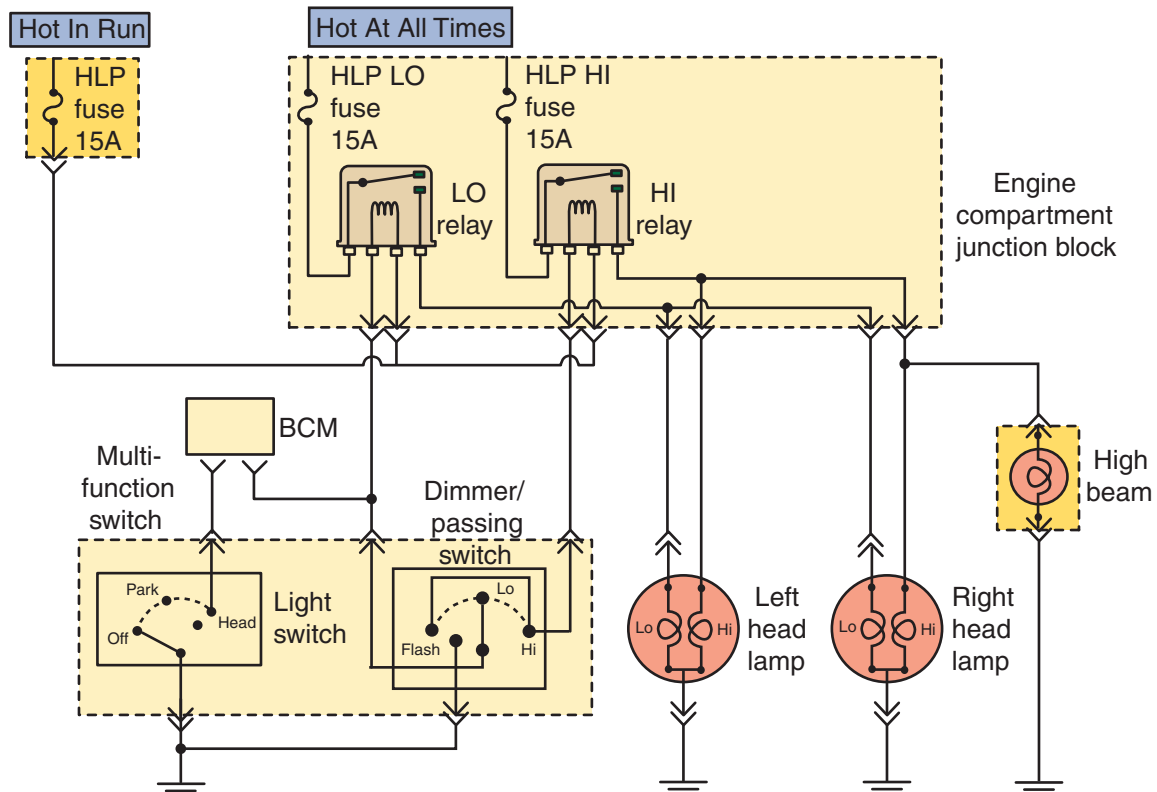

Figure 20-15 A schematic of a headlight circuit with switches.

Figure 20-16 An instrument panel light control switch. This switch also resets the trip odometer.

Figure 20-18 Most newer vehicles have the dimmer switch mounted on the steering column.

Figure 20-17 Some vehicles display a brightness scale on the instrument panel as the brightness control is moved.

Dimmer Switches

The **dimmer switch** provides a way for the driver to switch between high and low beams. A dimmer switch is connected in series with the headlight circuit and controls the current path to the headlights. The low-beam headlights are wired separately from the high-beam lamps. Often there is a relay for each set of beams. Newer vehicles have the dimmer switch on the steering column (**Figure 20-18**).

When the headlight switch is in the HEADLIGHT position, current flows to the dimmer switch. If the dimmer switch is in the LOW position, current flows through the low-beam circuit. When the dimmer switch is in the HIGH position, current flows to the high-beam circuit (see **Figure 20-15**).

The circuits just discussed have switches that control battery voltage and the bulbs have a fixed

ground. Many manufacturers use a system that relies on a groundside switch to control the headlights. In these systems, voltage is always available at the headlights. The headlight switch completes the circuit to ground and the headlights turn on. In these systems, the dimmer switch is also a ground control switch.

Daytime Running Lights

Canadian law requires that all new vehicles be equipped with **daytime running lights (DRL)** for added safety. This feature is also standard equipment on all new GM vehicles sold in North America. The system normally uses the vehicle's high-beam lights. The control circuit is connected directly to the vehicle's ignition switch so the lights are turned on whenever the vehicle is running. The circuit is equipped with a module that reduces 12-volt battery voltage to approximately 6 volts. This voltage reduction allows the high beams to burn with less intensity and prolongs the life of the bulbs. When the headlight switch is moved to the HEADLIGHT position, the module is deactivated and the lights work with their normal intensity and brightness. Applying the parking brake also deactivates the DRL system so the lights are not on when the vehicle is parked and the engine is running.

LED DRL Systems As a first step toward LED headlamps, Audi introduced LED DRLs in a separate unit. This move eliminates the need to drop the voltage to the normal headlamps for operation of the DRLs and therefore improves the vehicle's fuel economy. It is estimated that these lights consume more than 50% less power than the typical DRL. In addition, they use less space.

Concealed Headlights

Although not as common as they were a few years ago, concealed headlights are still found on some cars. Manufacturers use a concealed headlight system to improve the vehicle's aerodynamics and for style. Today, low profile headlight assemblies are being used instead of "pop-up" headlights.

When the headlight switch is moved to the HEADLIGHT position, the entire headlamp assembly pivots upward. This action is controlled by electric or vacuum motors.

The headlight switch for vacuum systems has vacuum motors attached to the headlight assemblies. When the switch is in the OFF position, engine vacuum is supplied to the motors to keep the headlight doors closed. When the headlight switch is moved to the HEADLIGHT position, a vacuum distribution valve vents the vacuum in the vacuum motors. This allows springs to open the doors. These systems are also equipped with a by-pass valve that allows the doors to be manually opened in case the system fails.

Electrically controlled systems use a torsion bar and a single motor to open both doors or have a separate motor for each headlight door. Current flow to the motors controls the opening and closing of the doors. Limit switches stop current to the motors when they are completely open or closed (**Figure 20-19**). The doors in electrically operated systems can also be manually opened.

Flash to Pass

Most steering column-mounted dimmer switches have an additional feature called flash to pass. This circuit illuminates the high-beam headlights even with the headlight switch in the OFF or PARK position. When the driver activates the flash to pass

feature, the contacts of the dimmer switch complete the circuit to the high-beam filaments.

Automatic Light Systems

These systems provide light-sensitive, automatic on-off control of the light normally controlled by the regular headlight switch. It consists of a light-sensitive **photocell sensor/amplifier** assembly and a headlight control relay. Turning the regular headlight switch on overrides the automatic system. In other words, automatic operation is not possible until the regular headlight switch is turned off.

In normal operation, the photocell sensor/amplifier, which is usually mounted under a group of perforated holes in the upper instrument panel pad or slotted holes in the defroster grille panel, is exposed to ambient light. As the light level decreases, the light sensor's resistance increases. When resistance increases to a preset amount, the amplifier applies power to the headlight relay coil. The headlights, exterior lights, and instrument illumination lights turn on. The lights remain on until the system is turned off or the ambient light level increases.

Some systems have two sensors to monitor the ambient light. The light sensors monitor the intensity of the ambient light at an extended angle above the vehicle and in a narrow angle to the front of the vehicle.

Most automatic light systems have a headlamp delay system as well. This system allows the headlamps to stay on for a period of time after the vehicle is stopped and the ignition switch is turned off. A variable switch (**Figure 20-20**) allows the driver to set the amount of time the headlights should remain on after the ignition is turned off. The system can typically be adjusted to keep the headlights on for up to 3 minutes after the ignition is turned off. Of course, the driver can turn off the delay system and the headlamps will shut off as soon as the ignition is turned off.

Customer Care

If the customer's car is equipped with an automatic light control system, point out the location of the perforated holes or slots. Warn the customer not to place any items that may block light from the sensor/amplifier assembly. Blockage causes erratic operation of the system. The photocell must always be exposed to an outside light to function properly.

High-Beam Detection This system automatically turns the high-beam headlights on or off according to conditions. A light sensor (commonly referred to as a camera) on the rearview mirror monitors the light in front of the vehicle (**Figure 20-21**). When it is dark enough, the system will switch the high beams on. They will stay on until the sensor detects the headlights or taillights of another car. At that time the high beams are switched off until the lights of the other vehicle are no longer detected. The absence of those lights causes the system to switch back to high beams. The system also fades the change from low to high to prevent abrupt changes to the light on the road ahead. The system is programmed to ignore bright lights near the road and reflections from roadside signs. GM calls this system the “IntelliBeam Intelligent High-Beam Headlamp Control System.”

Adaptive Headlights

Adaptive headlight systems are electronically controlled through inputs from the steering system and vehicle speed. They aim the lights in the direction the vehicle is turning (**Figure 20-22**). Currently there are

Figure 20-21 A photocell for an automatic lighting system.

Figure 20-22 A comparison of how the road is lit up with a conventional (top) headlamp system and an adaptive (bottom) system. *Courtesy of Chrysler LLC*

two basic system designs for adaptive lighting. Both are controlled by the vehicle's body control module (BCM). The systems respond in real time by responding to the vehicle's current steering angle, yaw rate, and road speed.

One design swivels the entire headlamp assembly. Bidirectional electric motors attached at the base of the assembly (**Figure 20-23**) can move the left headlamp up to 15 degrees to the left and 5 degrees to the right, and the right headlamp up to 5 degrees to the left and 15 degrees to the right. Some manufacturers use a variation of this design and rotate the headlamp's light projector, reflector, or lens, rather than the entire assembly.

Another design uses extra lamps that turn on according to steering angles. These cornering lights may be housed in the headlamp or fog light assembly, or they can be a separate unit. These lamps normally only turn on during low-speed turning.

Adaptive headlights can also be controlled by GPS navigation and digital road maps. With information about the road ahead, the system can anticipate curves in the road and move the headlamps to

Figure 20-23 A headlamp assembly for an adaptive headlight system. *Courtesy of Chrysler LLC*

illuminate curves before the driver starts to turn the steering wheel.

Further advancements in adaptive headlights include variable beam patterns. These systems will automatically change the headlight beams for current conditions, such as rain, snow, and fog.

Auxiliary Lights

Although the car's headlights are adequate in normal driving circumstances, some customers desire auxiliary lights for special conditions, such as driving in heavy fog. In addition to fog lights, driving lights, and passing lights, there are off-road lights, worklights, rooflights, decklights, deckbars, and handheld spotlights.

Auxiliary lights are easy to install when the manufacturer's instructions are carefully followed. The mounting of auxiliary lights, of course, varies according to the type of lights being installed. Before beginning, become familiar with the local regulations for auxiliary lights and adhere to them. These regulations can be obtained from your state's department of transportation. Also, always follow all federal, state, and local laws when aiming headlights, fog lights, and driving lights.

Driving Lights Driving lights typically use an H3 or H4 quartz halogen bulb and a high-quality reflector and lens to project an intense, pencil-thin beam of light far down the road.

Proper aiming of these lights is extremely important. They are used to supplement the high beams and should be used in conjunction with them. Driving lights should be wired so that they are off when

the high beams are off. One way to do this is to supply the controlling switch with current from the high-beam circuit, rather than from a circuit that is live all the time.

SHOP TALK

When adding auxiliary lights, make sure that the generator and wiring are heavy enough to handle the increased wattage requirement. Installing a higher output generator may be recommended, especially if other electrical accessories are also being installed. The choice of wire size should be based on the current of the load. Most light kits include a relay as a safeguard. A relay is used because the required current for these lights, especially halogen ones, can be quite high. It is not unusual that they require as much as 25 amperes.

Fog Lights Light does not penetrate fog well. Focus a powerful beam of light at the fog and all the driver sees is a powerful glare. To provide some light through the fog, fog lights are designed to send a flat, wide beam of light under the blanket of fog. This is why they are mounted low and are aimed low and parallel to the road. Because fog tends to reflect light back at the driver, fog lights are often fitted with yellow or amber lenses to reduce the discomfort caused by the glare. Some vehicles have OEM fog lights and are part of the normal lighting circuit.

HEADLIGHT SERVICE

When there is a headlight failure, it is typically caused by a burned-out bulb or lamp, especially if only one lamp fails. However, it is possible that the circuit for that one lamp has an open or high resistance. Check for voltage at the bulb before replacing a bulb. If there is no voltage present, the circuit needs work and the original bulb may still be good. If more than one lamp (including the rear lights) is not working, carefully check the circuit. A problem there is much more likely than having a number of burned-out bulbs. Of course, if the charging system is not being regulated properly, the high voltage will cause lamps to burn out prematurely.

Headlight Replacement

There can be slight variations in procedure from one model to another when replacing headlights. For instance, on some models the turn signal light assembly must be removed before the headlight can be

replaced. Overall, however, the procedure does not differ much from the following typical instructions.

Make sure the replacement bulb is the same type and part number as the one being replaced.

SHOP TALK

Because of the extremely high voltages involved, any work on xenon lighting should be done carefully and according to the manufacturer's recommendations.

PROCEDURE

Replacing Headlights

- STEP 1** Remove the headlight bezel-retaining screws. Remove the bezel. If necessary, disconnect the turn signal lamp wires.
- STEP 2** Remove the retaining ring screws from one or both lights.
- STEP 3** Remove the retaining rings.
- STEP 4** Remove the light from the housing. Disconnect the wiring connector from the back of the light (Figure 20-24).
- STEP 5** Push the wiring connector onto the prongs at the rear of the new light.
- STEP 6** Place the new light in the headlight housing. Position it so the embossed number in the light lens is on the top.
- STEP 7** Place the retaining ring over the light and install the retaining ring screws. Tighten them slightly.
- STEP 8** Check the aim of the headlight and adjust it, if necessary.
- STEP 9** Install the headlight bezel. Secure it with the retaining screws. Connect the turn signal lamp wiring (if it was disconnected).

SHOP TALK

Some manufacturers recommend coating the prongs and base of a new sealed beam with dielectric grease for corrosion protection. Use an electrical lubricant approved by the manufacturer.

HID Diagnosis and Service

Proper diagnosis of these systems depends on understanding how the circuit works. If only the low beams have a HID system, the headlights contain an arc tube and a transformer. The transformer increases the voltage so an arc can be established across the

Figure 20-24 After unplugging the old bulb, check and clean the contacts in the connector before installing the new bulb.

electrodes. The arc tube is where the arcing takes place. When the headlight switch is moved to the HEADLIGHT position, the ground for the low-beam relay is completed by the control computer (BCM). This energizes the relay, and battery voltage is applied to the transformer in each headlamp assembly. The transformer increases the voltage and starts the high-voltage arcing to light the bulb.

In bi-xenon systems, there is no separate high-beam bulb. Rather a solenoid with a shutter is used to redirect the light beams from the bulb. When the headlamp dimmer switch is moved to the high-beam position, ground is applied through the dimmer switch to the BCM. In response to this signal, the BCM completes the ground for the high-beam relay, energizing the relay. Battery voltage is then applied to the left and right high-beam solenoids that move the shutter.

Normal Delay Often the wait period for xenon lights to become fully illuminated is considered a problem. This is not a problem; it is normal. The transformers need high current to start and keep the lamps illuminating. This takes a little time; it takes 2 seconds to establish the arc and then another 30 seconds to have full illumination. Obviously, if it takes longer than that, there is a problem.

Bulb Color Another normal concern is the color of the light. HIDs produce a bluish-white light. However, some produce a light beam that appears pure white. This is not a problem, even if one side appears to be a different color than the other side. The color of the light depends on many normal factors. A worn bulb may have a dim pinkish glow. Often

replacement bulbs will have a yellowish-white look for the first 5 minutes when turned on. The lamps still provide the same amount of light as the originals and will provide a bluish light after about 100 hours of operation.

Bulb Replacement HID bulbs normally do not suddenly stop working. As the bulb wears, it will shut off and then turn back on. When the bulb is in the early stages of wear, this will happen very infrequently. As time goes on, the bulb will shut down and come on again rather frequently. This problem may progress to flickering until the system totally shuts down. Each manufacturer has a procedure for monitoring and diagnosing the system; always follow those.

Over time the resistance between the bulb's electrodes increases. This makes it harder for the transformer to maintain the arcing needed for light. When arcing is lost, the system will trigger the transformer to establish the arc again. This is what causes the light to flicker. It is best to replace the bulb before the lights constantly go on and off.

Every time the bulb shuts down, the transformer uses high current to reestablish the arc. The repetitive high current surges to the transformer damages the transformer. Eventually, the system will stop sending current to the transformer and the bulb will not work. When the lights have been flickering for a while the transformer should be replaced with a new bulb.

Headlight Adjustments

Headlights must be kept in adjustment to obtain the safest and best light beams on the road ahead. Headlights that are properly adjusted cover the correct range and afford the driver the proper nighttime view. Headlights that are out of adjustment can cause other drivers discomfort and sometimes create hazardous conditions.

Before adjusting or aiming a vehicle's headlights, make the following inspections to ensure that the vehicle is level. Any one of these conditions can result in an incorrect setting.

- The vehicle must be on a level floor.
- If the vehicle is coated with snow, ice, or mud, clean it, especially the underside. The additional weight can alter the riding height.
- Try to make the adjustment with the fuel tank half full; this should be the only load present on the vehicle.
- Worn or broken suspension components affect the setting, so check the springs or shock absorbers.

Figure 20-25 An example of headlight adjustment screws. Courtesy of Toyota Motor Sales, U.S.A., Inc.

- Inflate all tires to the recommended air pressure levels.
- Make sure the wheel alignment and rear axle tracking path are correct before adjusting the headlights.
- After placing the vehicle in position for the headlight test, push down on the front fender to settle the suspension.

Headlight assemblies have adjusting screws to move the headlight within its assembly to obtain correct headlight aim. Lateral or side-to-side adjustment is made by turning the adjusting screw at the side of the headlight (**Figure 20-25**). Vertical or up-and-down adjustment is made by turning the screw at the top of the headlight.

SHOP TALK

While adjusting headlight beams, make sure they meet the standards established by your local community, state, or province.

To properly adjust the headlights, their aim must be checked first. Many types of headlight aiming equipment are available (**Figure 20-26**). These aimers use mirrors with split images, like split-image finders on some cameras, and spirit levels to make exact adjustments. When using any mechanical aiming tool, follow the manufacturer's instructions. When headlight aiming equipment is not available, alignment can be checked by projecting the upper beam of each light on a screen or chart at a distance of about

Figure 20-26 A typical headlight aiming kit. Reproduced under license from Snap-on Incorporated. All of the marks are marks of their owners.

Figure 20-27 Acceptable beam patterns on a wall screen.

25 feet ahead of the headlight (**Figure 20-27**). The vehicle must be exactly perpendicular to the chart.

To mark the chart for reference, measure the distance between the centers of the headlights. Use this measurement to draw two vertical lines that correspond to the center of the headlights. Then draw a vertical centerline halfway between the two vertical lines. Measure the distance from the floor to the centers of the headlights. Subtract 2 inches from this height and draw a horizontal line on the screen at this new height.

With the headlights on high beam, the hot spot of each projected beam should be centered on the point of intersection of the vertical and horizontal lines on

the chart. If necessary, adjust the headlights vertically and laterally to obtain proper aim.

Some vehicles are equipped with indicators to help with adjustment. There is a horizontal indicator gear (**Figure 20-28**) at each headlamp assembly. Prior to making any adjustments, it is recommended that this indicator be at "0." A screwdriver is used to bring the gear back to "0." After this, the headlamps can be adjusted to specifications.

Many headlamps have a bubble level to aid vertical alignment. A horizontal gauge and magnifying window is located next to the bubble level as an aid for alignment (**Figure 20-29**). The vertical bubble level is used to compensate for vehicle ride height changes due to heavy loads. The bubble level is calibrated to the earth's surface; therefore, the vehicle must be on

Figure 20-28 Honda's headlight adjustment screws with an indicator.

Figure 20-29 Some vehicles have a bubble level at the headlights to aid in alignment.

level ground when the headlights are aimed. If the headlight beam projection appears high to oncoming traffic, check the alignment on an alignment screen. If the beam pattern is above or to the left of the specified location on the screen, adjust the headlights, then recalibrate the bubble level and magnifying window. Ideally, if the headlights are aligned, the bubble level and magnifying window will be centered. Never change the calibration of the magnifying window or bubble level if the headlights are out of alignment.

Normally, a previously properly aimed headlight does not need to be realigned after replacement of a bulb.

Auto-Leveling Headlamps

Some vehicles, primarily those equipped with xenon headlamps, have an automatic headlight leveling system. With this system there is no need to adjust the headlamps. However, if this system fails, the headlamps will not be properly aligned and the system must be diagnosed. Before diagnostics can take place, an understanding of how the system works is important.

The system keeps the headlights' aim within a prescribed range regardless of the vehicle's load and driving conditions. Each headlamp assembly has a headlamp leveling motor controlled by a headlamp control module. The control module is connected to motors at each headlamp and responds to demands by the BCM. The control module may be part of the lamp's transformer assembly. Based on inputs and its programming, the module determines the best headlight angle for the current conditions and orders that position to the electric motors. The motors, in turn, move the headlamp assembly.

The control module monitors inputs from position sensors at the control arms in the front and rear suspensions. As the suspension compresses and rebounds, the sensors' arms move and new signals are sent to the control module. The control module compares these inputs to information stored in its memory and sends out commands to adjust the aim of the headlamps, if needed.

The control module also receives inputs from a vehicle speed sensor. This allows the control module to know when the vehicle is accelerating or braking. During both of these events, the pitch or angle of the vehicle changes.

Diagnosis Diagnosis is done with a scan tool. The scan tool can be used to order the motors to move up and down. With the ignition on, do this and observe the headlamps. If they do not move, test the motors. If the motors move, check the voltage of the front and rear leveling position sensors. Normally the voltage

should be between 0.5 and 4.9 volts. If the reading is not within the specified range, check the sensors.

The scan tool may also retrieve fault codes for the system. Possible fault codes can be set for a short to ground, open/high resistance, short to voltage, and abnormal signal performance for the following areas:

- Front and rear headlamp leveling sensor
- Front and rear headlamp leveling sensor 5-volt reference
- The headlamp leveling motor control circuits on both sides

The motor assembly is checked with an ohmmeter. With the ignition off, disconnect the electrical connector at each headlamp leveling motor. Take resistance readings across the various terminals of the connector and compare your reading to the specifications. The leveling sensors are checked with a voltmeter. First the reference voltage is checked at the specified terminals. If the voltage is higher than normal, there is a short to ground, an open, or high resistance in the circuit. If all circuits test normal, the appropriate headlamp leveling sensor may be bad.

Automatic Headlight System Diagnosis

Automatic headlight systems respond to changes in outside light levels. A photocell, normally in the vehicle's dash, sends a signal to the BCM. The BCM energizes the low-beam circuit when it is appropriate. If the headlamps turn on when the headlight switch is placed on the position but not when it is in "auto," the problem is in the auto circuit. Check the area around the photocell for anything that may be blocking light from the sensor. Check all connections in the system. The circuit normally contains a relay and amplifier along with the photocell. Each should be tested according to the procedures given by the manufacturer.

The photocell, or camera, must be properly aligned in order for the system to respond to the lights of oncoming vehicles and not lights coming from the far sides of the road. This typically is a very involved process and the procedures given by the manufacturer must be followed. This involves many measurements and conducting tests with a scan tool (**Figure 20-30**).

Most systems also keep the lights on for a short time after the vehicle has been parked. The controlling device for this feature is a potentiometer incorporated into the headlamp switch. When the delay feature is not working properly, begin testing at the timer control.

Adaptive Headlight Diagnosis

The operation of the adaptive headlight system is controlled by the headlamp control module.

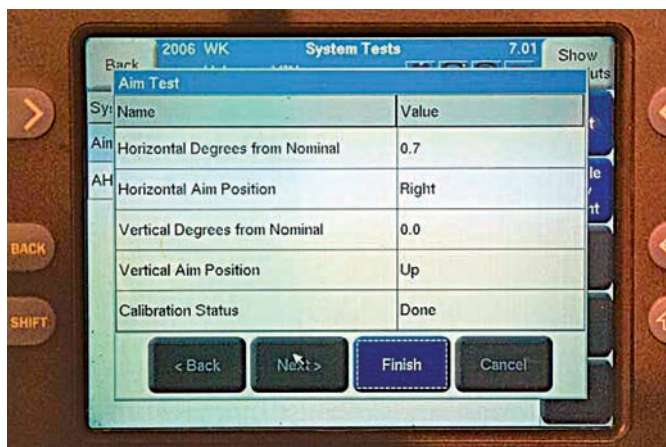

Figure 20-30 Calibration of the photocell includes a check with a scan tool.

Therefore, diagnosis begins with a scan tool. Because the system responds to many inputs, each one should be monitored.

The headlamp control module receives serial data from the engine control module, transmission control module, electronic brake control module, and body control module. The control module calculates the desired headlamp angle and orders the actuators or motors, at each headlight to move the headlamps. The control module also monitors the condition of the motor control circuits. If a problem is detected, a DTC will be set and a message displayed in the instrument panel to alert the driver of a problem.

OTHER LIGHT BULBS

There are several types of light bulbs used in today's vehicles (**Figure 20-31**). Each design has a unique purpose and a unique way it fits into its socket. This prevents the use of the wrong design. However, within a particular design, there may be different bulbs, each with its own power rating. Whenever replacing a bulb, make sure it is the exact replacement.

- A,B** MINIATURE BAYONET FOR INDICATOR AND INSTRUMENT LIGHTS

SHOP TALK

The current trend is to use LEDs rather than standard bulbs in many different lighting systems. Taillights, turn signals, hazard lights, side lights, parking lights, and fog lamps may use an LED or a cluster of LEDs. When a light is not working, make sure you know if an LED is being used before getting a new bulb or beginning diagnostics.

Most bulbs fit into sockets and are held in place by spring tension or mechanical force. Bulbs are coded with numbers for replacement purposes. Bulbs with different code numbers might appear physically similar but have different wattage ratings.

Light Circuits

Light systems normally use one wire to the light, making use of the car body or frame to provide the ground. Because many of the manufacturers are now using plastic sockets and mounting plates (as well as plastic body parts) to reduce weight, many lights must now use two wires, the second one for the ground. Many bulbs have a single filament.

Double-filament bulbs are actually two separate bulbs in one casing; therefore, they have two hot wires. Some are grounded through their case and others require a third wire for ground.

Many light circuits are switched or controlled on the power side of their circuit; however, there are ground-controlled circuits. Knowing how the light is controlled is important for diagnostics.

INTERIOR LIGHT ASSEMBLIES

The types and numbers of interior light assemblies used vary significantly from one vehicle to another (**Figure 20-32**). Following are the more common ones.

Engine Compartment Light Operating the hood causes the engine compartment light mercury switch to close and light the underhood area. Some pickup trucks and SUVs are equipped with an underhood retractable magnetic base lamp mounted on a reel. The lamp can be used anywhere around the vehicle.

Glove Box Light Opening the glove box door closes the glove box light switch contacts and the light comes on.

Luggage Compartment Light The light is mounted in the underside of the trunk deck lid in the luggage compartment.

Figure 20-32 Full interior illumination is available with this light setup. Courtesy of Chrysler LLC

Trunk Lid Light Lifting the trunk lid causes the light mercury switch to close and the light to come on.

Vanity Light Pivoting the sun visor downward and opening the vanity mirror cover causes the vanity light switch contacts to close and the light to come on.

Courtesy Lights Vehicles may have courtesy lights in the door trim panels, under each side of the instrument panel, above the foot wells, or in the center of the headlining. Their sole purpose is to allow light inside the vehicle. They are illuminated when one of the doors is opened, by rotating the headlight switch to the full counterclockwise position, or by depressing the designated switch. **Figure 20-33** is a wiring diagram of a typical courtesy light circuit. The courtesy lights are also turned on by the illuminated entry or keyless entry systems, if the vehicle is equipped with one or both of these. LEDs are often used for interior lighting (**Figure 20-34**).

Typically, power is supplied from the fuse block to the courtesy lights. The ground is controlled by the position of the door switch. The door switches are held in an open position and do not provide for a ground circuit. When the door is opened, a spring

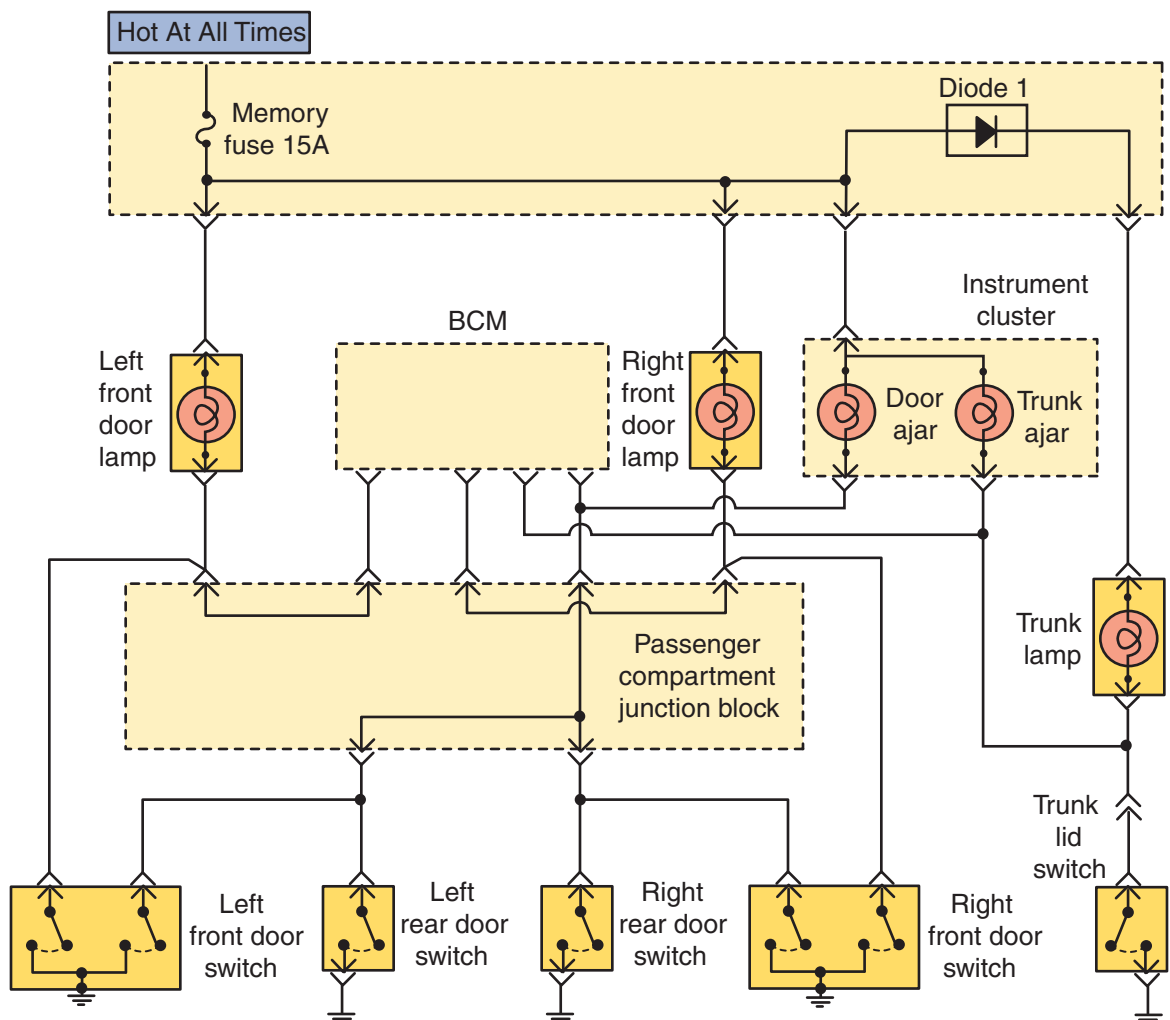

Figure 20-33 A typical courtesy light circuit.

Figure 20-34 An example of using LEDs for interior lights. *Courtesy of Chrysler LLC*

pushes the switch closed to ground the circuit, and the courtesy lights come on. Interior and courtesy lights rarely give any trouble. However, if they do not operate, check the fuse, bulb, switch, and wiring.

Dome/Map Light Map lights are typically located on each side of the dome/map light housing. They are operated independently of the dome light by switches located at each map light. The dome light (**Figure 20-35**) is actuated by a switch or along with the courtesy lights when the door is opened.

Illuminated Entry System This system assists vehicle entry during the hours of darkness by illuminating the door lock cylinder so it may be easily located for key insertion. The vehicle interior is also illuminated by the courtesy lights.

Most of these systems have an electronic actuator module, an illuminated door lock cylinder, a door latch switch, and wiring harness. The system is activated by raising the outside door handle, by depressing a key on the key fob, or by entering a code on the keyless entry system. This action momentarily closes a switch mounted on the door latch mechanism, which completes the ground circuit of the electronic actuator module and switches the system on. The vehicle interior lights turn on, and both front

Figure 20-35 A dome light.

door lock cylinders are illuminated by a ring of light around the area where the key enters. This illumination remains on for approximately 25 seconds and then automatically turns off. During this 25-second period, the system can be manually deactivated by turning on the ignition switch.

REAR EXTERIOR LIGHTS

The rear of a vehicle has many different lights. These include the taillights, turn signal and hazard lamps, brake lights, a center high-mounted stoplight, side marker lamps, reverse or back-up lights, and license plate lamps. Many of them are incorporated in the taillight assembly. Rear lighting is definitely part of the overall style of the vehicle and most make a styling statement (**Figure 20-36**).

Turn, Stop, and Hazard Warning Light Systems

Power for the turn (directional signal), stop, and hazard warning light systems is provided by the fuse panel (**Figure 20-37**). Each system has a switch that

Figure 20-36 A stylish taillight assembly using LED technology.

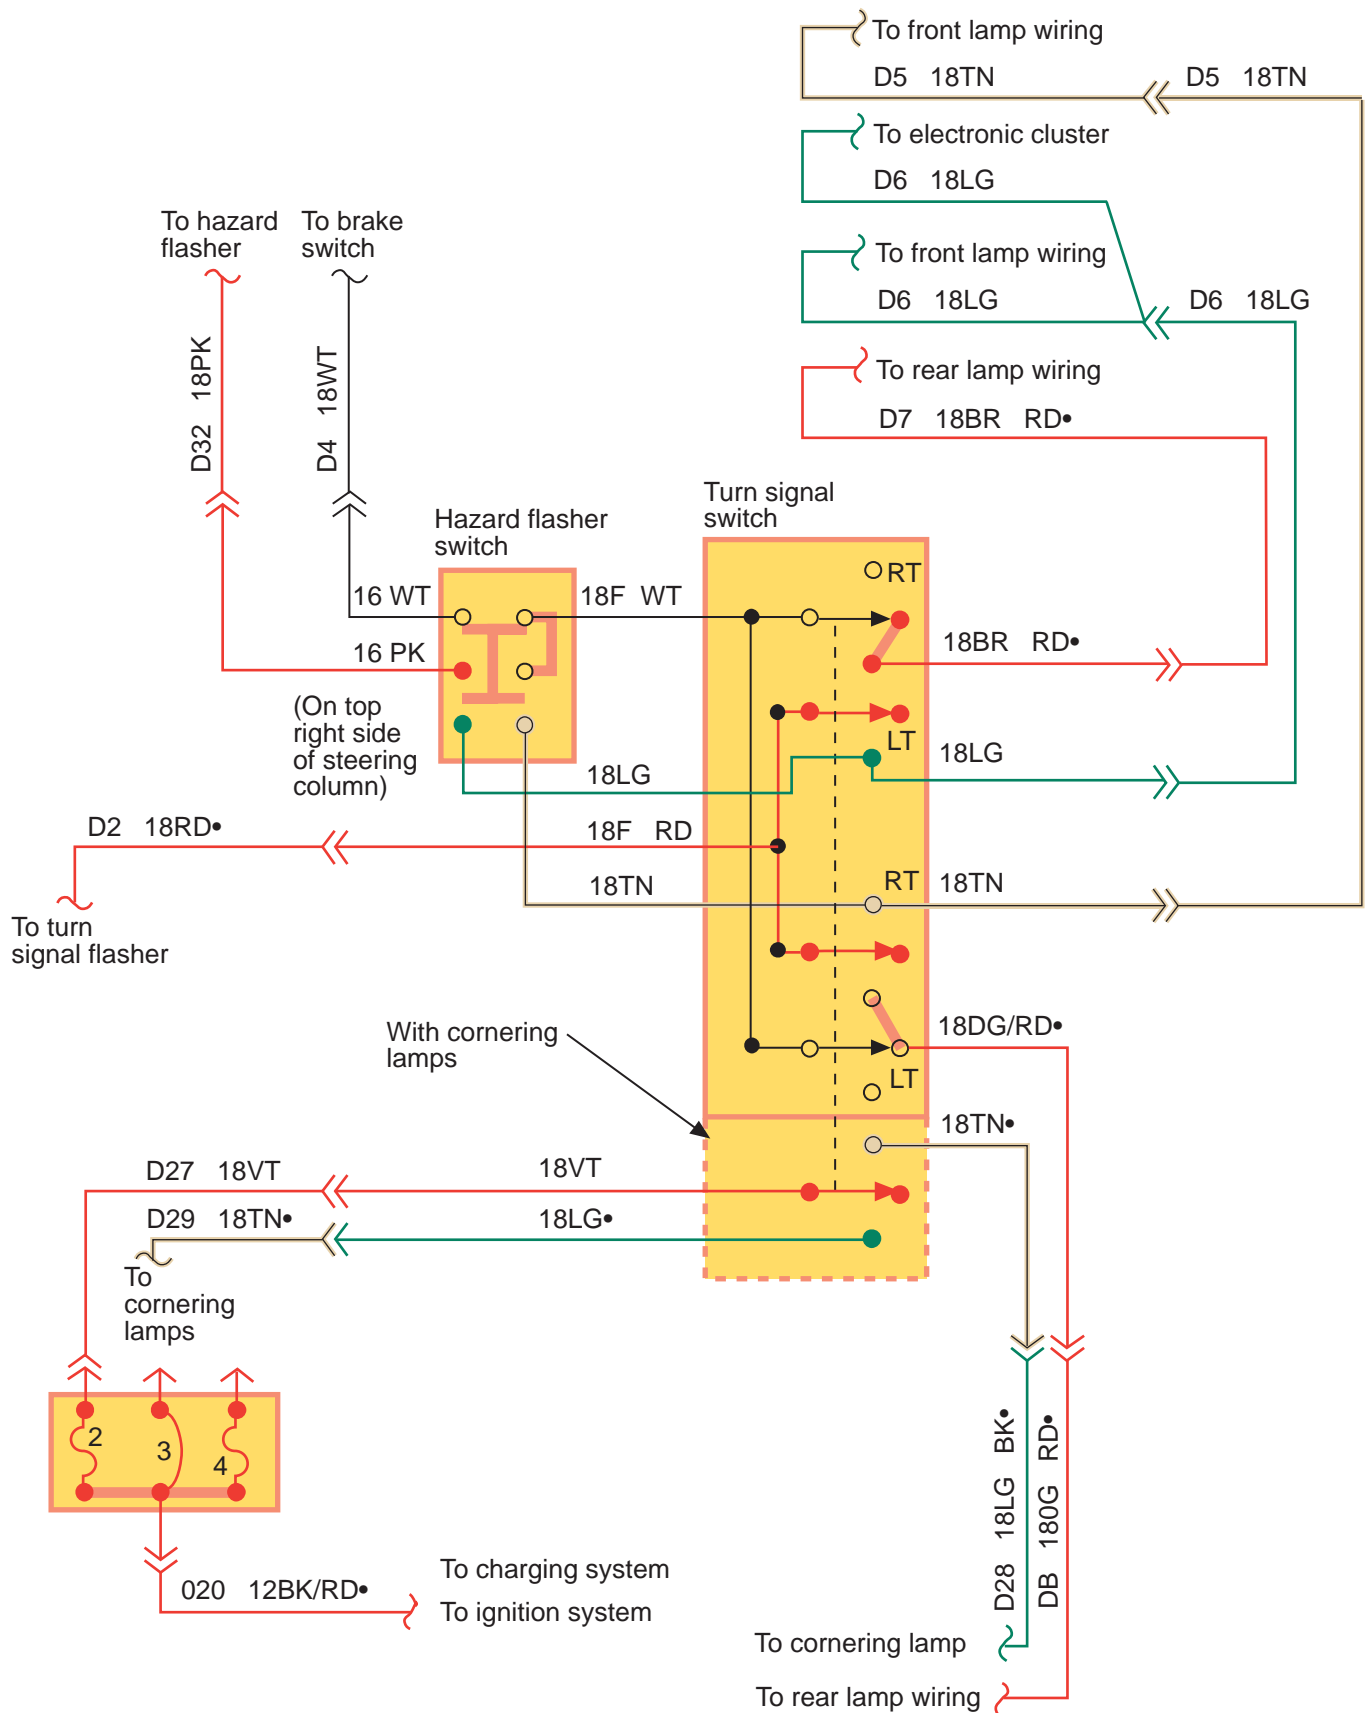

Figure 20-37 Turn signal circuit for a two-bulb system. *Courtesy of Chrysler LLC*

must close to turn on the lights in the circuit. Hazard lights are commonly referred to as 4-way flashers because the lights at all four corners of the vehicle will flash when the circuit is turned on.

The turn signal and hazard light switches on many current vehicles are part of a **multifunction switch**. When the turn or directional signal switch is activated, only one set of the switch contacts is closed—left or right. However, when the hazard switch is activated, all contacts are closed and all turn signal lights and indicators flash together and at the same time.

The power for the turn signals is provided through the fuse panel, but only when the ignition switch is on. The hazard lights are also powered through the fuse panel; however, they have power at all times regardless of ignition switch position.

Side markers are connected in parallel with the feed circuit (from the headlight switch) for the filaments of the front parking lights and rear taillights.

What a multifunction switch controls depends on the make, model, and year of the vehicle. Some control the directional signals and serve as the dimmer switch. Others control the turn and hazard signals and serve as the headlight, dimmer, windshield wiper, and windshield washer switch.

This switch is not repairable and must be replaced if defective. Photo Sequence 18 outlines the typical procedure for removing a multifunction switch. Some of the steps shown in this procedure may not apply to all types of vehicles; always refer to the service manual before removing this switch. Also carefully study the procedures beforehand and identify any special

Figure 20-38 A typical turn signal flasher. Courtesy of Ford Motor Company

warnings that should be adhered to, especially those concerning the air bag.

Flashers **Flashers** are components of both turn and hazard systems. They contain a temperature-sensitive bimetallic strip and a heating element (**Figure 20-38**). The bimetallic strip is connected to one side of a set of contacts. Voltage from the fuse panel is connected to the other side. When the left turn signal switch is activated, current flows through the flasher unit to the turn signal bulbs. This current causes the heating element to emit heat, which in turn causes the bimetallic strip to bend and open the circuit. The absence of current flow allows the strip to cool and again close the circuit. This intermittent on/off interruption of current flow makes all left turn signal lights flash. Operation of the right turn is the same as the operation of the left turn signals.

Turn signal flashers are installed on the fuse panel on current car models and most current truck models (**Figure 20-39**). However, on earlier models this is not

Figure 20-39 A common location for the flashers in the fuse panel. Courtesy of Ford Motor Company

Removing a Multifunction Switch

P18-1 The tools required to test and remove a multifunction switch are fender covers, battery terminal pliers and pullers, assorted wrenches, Torx driver set, and an ohmmeter.

P18-2 Place the fender covers over the fenders of the vehicle.

P18-3 Loosen the negative battery clamp bolt and remove the battery clamp. Place the cable where it cannot contact the battery.

P18-4 Remove the shroud retaining screws and remove the lower shroud from the steering column.

P18-5 Loosen the steering column attaching nuts. Do not remove the nuts.

P18-6 Lower the steering column just enough to remove the upper shroud.

P18-7 Remove the turn signal lever by simply rotating the outer end of the lever. Then pull it straight out.

Removing a Multifunction Switch *(continued)*

P18-8 Peel back the foam shield from the turn signal switch.

P18-9 Disconnect the turn signal switch electrical connectors.

P18-10 Remove the screws that attach the switch to the lock cylinder assembly.

P18-11 Disengage the switch from the lock assembly.

P18-12 Use an ohmmeter to test the switch. Check for continuity when the dimmer switch is in the low-beam position.

P18-13 When the switch is in the low-beam position, the circuit should be open between the high-beam terminals.

P18-14 Also check the other terminals and circuits that should be open when the dimmer switch is in the low-beam position.

P18-15 With the switch in the high-beam position, there should be continuity across the high-beam circuit. Also check for continuity across the other circuits that should be open when the switch is in the high-beam position.

P18-16 When the dimmer switch is placed in the flash-to-pass position, there should be continuity across those designated terminals and an open across the others.

true. Hazard flashers are also mounted in various locations. Refer to the service manual for locations on the model being serviced.

A testlight can be used to determine which flasher is used for the turn signals and which is used for the hazard warning light. An easier way is to turn on both the directionals and the hazards. This activates both flasher units. By removing one of the flashers, the affected circuit no longer flashes. Therefore, that flash unit controls that particular circuit. If the turn signals fail to operate and the fuse is good, the flasher has probably failed.

Occasionally, the flasher does not flash as fast as it once did, or it flashes faster. This is also cause for replacement. If it flashes too slowly or not at all, check for a burned-out bulb first.

A flasher features two or three prongs that plug into a socket. Just pull the flasher out of the socket and replace it with a new one.

Flashers are designed to operate a specific number of bulbs to give a specific **candlepower** (brightness). If the candlepower on the turn signal bulbs is changed, or if additional bulbs are used (if a vehicle is hooked up to a trailer, for instance), a heavy-duty flasher must be used. This usually fits the socket without modifications. Although heavy-duty flashers will operate additional bulbs, they have one big disadvantage and should not be used unless it is necessary. These flashers will not cause the turn signals to flash slower if a bulb burns out. When a turn signal bulb fails, the driver has no idea that it did.

! WARNING!

The flasher unit for turn signals should not be switched with a flasher unit for the hazard lights.

Some newer vehicles have a combination flasher unit that controls the flash rate of both the turn signals and the hazard lights. These combination flashers are electronic units (**Figure 20-40**). The actual turning off and on of the lights is caused by the cycling of a transistor. This type of flasher also senses when a bulb is burned out and causes the remaining bulbs on that side to flash faster. Because this flasher is an electronic device, it cannot be tested with normal test equipment. The only test of the flasher is to substitute it with a known good one. If the lights flash normally,

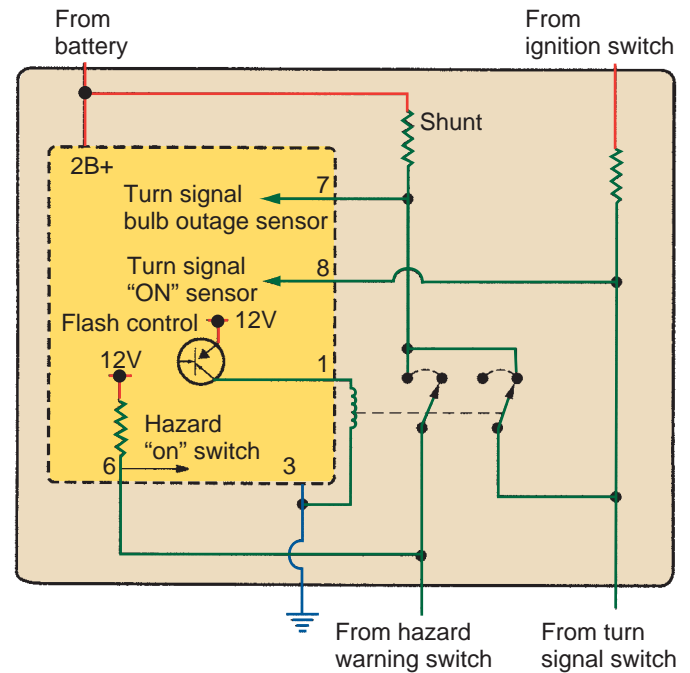

Figure 20-40 A typical electronic combination flasher unit. *Courtesy of Chrysler LLC*

the original flasher unit was bad and needs to be replaced.

Brake Lights

The brake (stop) lights are usually controlled by a stoplight switch that is normally mounted on the brake pedal arm (**Figure 20-41**). Some cars are equipped with a brake or stoplight switch mounted on the master cylinder, which closes when hydraulic pressure increases as the brake pedal is depressed. In either case, voltage is present at the stoplight switch at all times. Depressing the brake pedal causes

Figure 20-41 A stoplight switch located at the brake pedal assembly.

Figure 20-42 A CHMSL with LEDs.

the stoplight switch contacts to close. Current can then flow to the stoplight filament of the rear light assembly. These stay illuminated until the brake pedal is released.

In addition to the stoplights at the rear of the vehicle, all late-model vehicles have a center high-mounted stoplight (CHMSL) that provides an additional clear warning signal that the vehicle is braking (**Figure 20-42**). Federal studies have shown the additional stoplights to be effective in reducing the number and severity of rear collisions. The high-mounted stoplight is activated when current is applied to it from the stoplight switch. It stays illuminated until the brake pedal is released. When its contacts are closed, the stoplight switch can also provide current to the speed control amplifier, anti-lock brake control module, and the electric brake controller connector.

LED Lights

Some vehicles use neon lamps and/or LEDs for tail, brake, and turn signal lights. Neon lights are more energy efficient and turn on more quickly than regular lights. Because neon bulbs have no filament, the neon bulb will last longer than a conventional light bulb.

Whereas conventional bulbs take around 200 milliseconds to reach their full brightness, neon bulbs turn on within 3 milliseconds. The importance of this time difference is that it gives the driver behind the vehicle an earlier warning to stop. This early warning can give the approaching driver 19 more feet for stopping when driving at 60 miles per hour.

LEDs offer the same advantages as neon bulbs and turn on even quicker because they do not need to heat up to illuminate. LEDs achieve their full output in less than 1 millisecond. Several LEDs are placed behind the lens and are activated at the same time to give a bright illumination of the light assembly. LEDs also require a much smaller space so they are much less intrusive in the trunk. LEDs have a long operating life and provide a more precise contrast and signal pattern, thus attracting attention much more effectively.

Using the same basic technology as LEDs, laser-lit taillights consume seven times less power than incandescent sources. These savings are extremely important for electric vehicles. The light waves of a laser light beam move in the same direction and the light is all the same color. When used with rear exterior lights, fiber optics carry red light from a diode laser to a series of mirrors, which send the beam across a thin sheet of acrylic material.

Adaptive Brake Lights This system can select one of two available brake light areas for illumination: Moderate braking activates the standard brake lights incorporated within the taillight assemblies as well as the center high-mount brake light. Under intense braking and during all braking maneuvers with active ABS intervention, additional lamps are lit, thereby changing the size of the brake lights and their intensity (**Figure 20-43**). By increasing the brake lights' illuminated surface area, the system alerts drivers of following vehicles that the vehicle in front has started braking and decelerating at a rapid rate. This warning allows the driver of the following vehicle to react more quickly and reduces the danger of a rear impact.

An electronic control unit processes signals supplied by the speed sensor and the antilock brake system. It then uses these data to calculate the intensity of the braking as reflected by the vehicle's rate of deceleration.

Figure 20-43 (Left) The normal illumination of the brake lights. (Right) The illumination during hard stops. Courtesy of BMW of North America, LLC

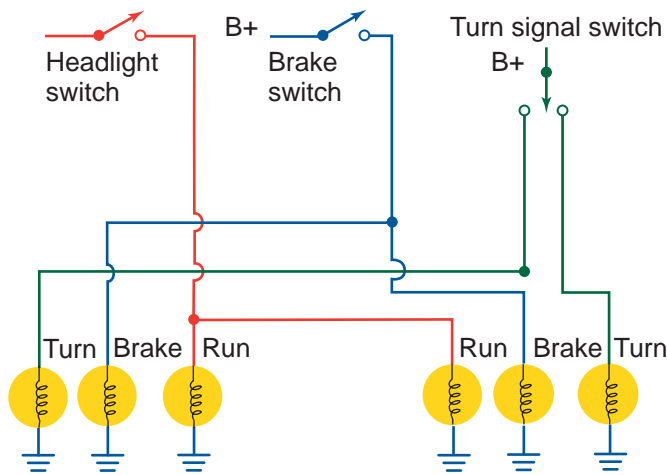

Figure 20-44 A typical three-bulb taillight circuit.

USING SERVICE INFORMATION

In addition to the taillight system, the rear of vehicles have many other lighting circuits. Most cars have brake lights, run lights, turn signals, and back-up lights. Let us look at these circuits (**Figure 20-44**) and see that their diagnosis is very simple once you are aware of how they appear in the service manual. Start with the brake lights. The easiest circuit to look at first is the three-bulb circuit found on many vehicles. The drawing shows a typical taillight circuit, which contains three separate filaments for each side of the rear of the vehicle. There is a separate filament for each function: brake, turn, and run. A constant source of fused B+ is made available to the brake switch. The brake switch is usually located on the brake pedal and is closed by pushing down on the brake pedal. B+ is now available to the bulbs, wired in parallel, at the rear of the vehicle. Releasing the brake pedal allows the spring-loaded normally open (NO) switch to open and turn the brake lights off. This is a simple circuit that requires only a 12-volt testlight or a voltmeter for diagnosis. The most common cause of failure is bulbs that burn out. Testing for B+ and ground at the bulb socket should verify the circuit. If B+ is not available at the socket, test for power at each connector, moving back toward the switch until it is found. Repair the open. Do not forget that the circuit is only hot if the brake pedal is depressed.

Back-Up Lights When the transmission is placed in reverse gear, back-up lights are turned on to illuminate the area behind the vehicle and to let other drivers know that the vehicle is in reverse. The major components in the system are the back-up light switch and the lights.

Power for the back-up light system is provided by the fuse panel. When the transmission is shifted to reverse, the back-up light switch closes and power flows to the back-up lights. That is, any time the transmission is in reverse, current flows from the fuse panel through the back-up light switch to the back-up lights. On many vehicles, the fuse that protects the back-up light system also protects the turn signal system.

In general, vehicles with a manual transmission have a separate switch. Those with an automatic transmission use a combination neutral start/back-up light switch. The combination neutral start/back-up light switch used with automatic transmissions is actually two switches combined in one housing. In park or neutral, current from the ignition switch is applied through the neutral start switch to the starting system. In reverse, current from the fuse panel is applied through the back-up light switch to the back-up lights.

The back-up light system is relatively easy to troubleshoot. On vehicles that use one fuse to protect both the turn signals and the back-up lights, the fuse can be checked. If the back-up lights are not working, check turn signal operation. If they work, the fuse is good. Check for power at the back-up light switch input and outlet with the transmission in reverse. (Make sure the parking brake is set.)

If the switch is okay, or there is no power to the switch, check the wiring—especially the connectors. If the back-up lights stay on when the transmission is not in reverse, suspect a short in the back-up light switch.

BASIC LIGHTING SYSTEM DIAGNOSIS

Light problems can be solved by simply replacing bulbs. A bulb can be quickly checked with a powered testlight or an ohmmeter. Connect the testlight across two of the bulb's terminals (**Figure 20-45**). If there is continuity, the bulb is good.

Figure 20-45 A bulb can be quickly checked with a continuity tester.

When a burnt-out bulb is not the problem, corroded or loose wiring is the next most common problem. All wiring connections should be clean and tight; light assemblies need to be securely mounted to provide a good ground. **Table 20-1** is a basic troubleshooting guide for lighting problems.

TABLE 20-1 GENERAL LIGHTING TROUBLESHOOTING GUIDE

Concern	Most Probable Cause
One light does not work	Bad bulb Open in that circuit
One light is dim	High resistance in the power or ground circuit
All lights in a circuit do not work	Open in the power or ground circuit Blown fuse Bad (control) switch
All lights in a circuit are dim	High resistance in the power or ground circuit
Flickering lights	Loose electrical connection A circuit breaker that is kicking out because of a short
One low-beam headlamp does not work	Bad bulb High resistance in the power or ground circuit
Both low beams do not work	Open in the power or ground circuit Bad (control) switch Blown fuse Bad bulbs due to overcharging
One high-beam headlamp does not work	Bad bulb High resistance in the power or ground circuit
Both high beams do not work	Open in the power or ground circuit Bad (control) switch Blown fuse Bad bulbs due to overcharging
Slow turn signal operation	Bad flasher unit High resistance in the power or ground circuit Incorrect bulb
Turn signal on one side does not work	Bad bulb High resistance in the power or ground circuit

Bulb Replacement

When replacing a bulb, make sure it is the correct replacement bulb. Using the wrong bulb can cause problems, such as an incorrect blink rate. Inspect the bulb socket. Often moisture gets into a bulb socket and causes corrosion at the electrical contacts in the socket. At times, the corrosion can be removed with sandpaper. Other times, the socket or light assembly should be replaced.

Light bulbs are contained in an assembly and access to the bulb is gained by reaching around the rear of the assembly and removing the socket. Other assemblies require the removal of the light's outside lens. With the lens removed, the bulb is removed from the front. While doing this, inspect the lens and gasket for damage and replace any damaged parts. If the lens is not sealed, dirt and moisture can enter the assembly and cause problems in the future.

On some light fixtures, the light assembly must be removed and the bulb and socket are removed from the rear of the assembly. Do not remove the lens from the assembly. It is a sealed unit and dust and other contaminants can cause serious damage to the reflector. Also, never attempt to clean the reflector. Wiping its surface can seriously reduce the light's brightness.

Bulbs are held in their sockets in a number of ways. Some bulbs are simply pushed into and pulled out of their sockets (**Figure 20-46**), and some are screwed in and out. Some bulbs must be depressed and turned counterclockwise to remove them.

Figure 20-46 Many light bulbs are pulled out or pushed into their sockets.

CASE STUDY

A customer complains that the turn signals on his vehicle do not operate normally on the right side but work correctly on the left side.

The technician notices that the right front bulb lights but does not blink and the right rear does not work at all when the right turn signals are activated. He tests for power to the right rear with a testlight and the testlight blinks. He performs a voltage drop test and finds that the right rear bulb has an open circuit in its ground circuit. He repairs the ground and this system now works fine.

Turn signal circuits are frequent sources of difficulties. Their diagnosis, however, is not difficult and can usually be done with a testlight or DMM. Look at the common circuits, starting first with the flasher unit. The flasher is actually a type of circuit breaker, which is an overload protection device designed to open the circuit when excessive heat is developed from high current flow. Flashers are normally mounted in the fuse box and are made up of a fixed contact and a movable bimetallic contact. In the preceding case, not enough current was flowing through the right-side bulbs to operate the flasher when the right turn signals were activated. This was caused by the open ground circuit. The decreased current never heated the flasher unit enough to cause the front turn signal to blink. Of course, the rear bulb would not light because there was no ground.

KEY TERMS

Candlepower

Composite headlight

Daytime running lights
(DRL)

Sealed-beam

Xenon headlamps

SUMMARY

- Headlight systems consist of two or four sealed-beam, halogen, or xenon bulbs.
- The headlight switch controls the headlights and all other exterior lights, with the exception of the turn signals, hazard warning, and stoplights.
- Dimmer switches allow the driver to select high or low headlight beams.
- Many vehicles have daytime running lights, which are typically normal headlamps powered by low voltage.
- Automatic headlight systems switch the headlights from high beam to low beam in response to current lighting conditions.
- Headlights must be kept in adjustment to obtain maximum illumination for safe driving.
- There are a number of interior lights found on today's vehicles. These vary with the make or model of the vehicle.
- The rear light assembly includes the taillights, turn signal/stop/hazard lights, high-mounted stoplight, rear side marker lights, back-up lights, and license plate lights.
- Flashers are used in turn signal, hazard warning, and side marker light circuits.
- The back-up light system illuminates the area behind the vehicle when it is put in reverse gear.
- Replacement light bulbs should be an exact match of the originals.

REVIEW QUESTIONS

1. What lighting systems are controlled by the headlight switch?
2. What is a CHMSL?
3. *True or False?* HID lamps produce more heat and white light than a halogen bulb.
4. *True or False?* The headlights on many adaptive headlight systems can swivel up to 5 degrees in the direction the vehicle is turning.
5. *True or False?* Many turn signal flasher units contain a temperature-sensitive bimetallic strip and a heating element.
6. List five things that should be done prior to aligning the headlights.
7. What are the most probable causes for one low-beam headlamp not working?

8. How many wires are normally connected to a double-filament light bulb?
9. Circuits that can energize both the high and low beams even if the headlight switch is off are known as _____ circuits.
 - a. flash-to-pass c. dimmer
 - b. mercury d. retractable
10. Why do some manufacturers protect the headlamp circuit with a circuit breaker instead of a fuse?
11. What kind of headlight does not have a filament?
12. What is the primary tool used to diagnose an auto-leveling headlamp system?
13. Which of the following would probably *not* cause the headlights on both sides of the vehicle not to work?
 - a. an open in the power or ground circuit
 - b. a bad (control) switch
 - c. a blown fuse
 - d. low generator output
14. The stoplight switch is normally mounted on the _____.
 - a. instrument panel
 - b. transmission
 - c. brake pedal arm
 - d. none of the above
15. Which of the following is *not* a true statement about LED-based lights?
 - a. LEDs achieve their full output in about 200 milliseconds.
 - b. LEDs require a much smaller space so they are much less intrusive in the trunk.
 - c. LEDs have a long operating life.
 - d. LEDs provide a more precise contrast and signal pattern, thus attracting attention much more effectively.
2. Technician A says that the condition of the vehicle's springs and shocks should be checked before aligning a headlight. Technician B says that the vehicle should have a full tank of fuel when its headlights are being adjusted. Who is correct?
 - a. Technician A c. Both A and B
 - b. Technician B d. Neither A nor B
3. Composite headlights are being discussed: Technician A says that they have replaceable bulbs. Technician B says that a cracked or broken lens will prevent the operation of a composite headlamp. Who is correct?
 - a. Technician A c. Both A and B
 - b. Technician B d. Neither A nor B
4. While troubleshooting a brake light problem: Technician A says that when the pedal is depressed the brake lights should come on. Technician B says that on some systems only part of the brake light should illuminate when there is slight pressure on the brake pedal. Who is correct?
 - a. Technician A c. Both A and B
 - b. Technician B d. Neither A nor B
5. Technician A says that a sealed-beam headlight that is cracked should be replaced. Technician B says that cracking or breaking of the housing or lens does not prevent a halogen bulb from working. Who is correct?
 - a. Technician A c. Both A and B
 - b. Technician B d. Neither A nor B
6. Technician A says that if the turn signals blink faster than normal, the problem may be a burned-out bulb on that side of the vehicle. Technician B says that if the turn signals blink slower, the problem may be a burned-out light bulb on that side of the vehicle. Who is correct?
 - a. Technician A c. Both A and B
 - b. Technician B d. Neither A nor B

ASE-STYLE REVIEW QUESTIONS

1. While troubleshooting a headlight problem: Technician A says that when one headlamp does not work, the problem is probably a burned-out bulb or lamp. Technician B says that you should check for voltage at the bulb before replacing a bulb. Who is correct?
 - a. Technician A c. Both A and B
 - b. Technician B d. Neither A nor B
7. Technician A says that flickering vehicle lights can be caused by a circuit breaker that is kicking out due to a short. Technician B says that flickering vehicle lights can be caused by a loose electrical connection. Who is correct?
 - a. Technician A c. Both A and B
 - b. Technician B d. Neither A nor B
8. The turn signals operate in the left direction only: Technician A says that the flasher unit is bad.

Technician B says that the fuse is probably blown. Who is correct?

- | | |
|-----------------|--------------------|
| a. Technician A | c. Both A and B |
| b. Technician B | d. Neither A nor B |
9. The right back-up lamp is dim: Technician A says that the back-up lamp switch may have high resistance. Technician B says that the back-up lamp fuse may have corroded terminals. Who is correct?
- | | |
|-----------------|--------------------|
| a. Technician A | c. Both A and B |
| b. Technician B | d. Neither A nor B |
10. When the headlights are switched from low beam to high beam, all headlights go out: Technician A says that the problem may be a bad dimmer switch. Technician B says that the ignition switch may be bad. Who is correct?
- | | |
|-----------------|--------------------|
| a. Technician A | c. Both A and B |
| b. Technician B | d. Neither A nor B |

ELECTRICAL INSTRUMENTATION

OBJECTIVES

- Describe the two types of instrument panel displays.
- Know the purpose of the various gauges used in today's vehicles and how they function.
- Describe the operation of the common types of gauges found in an instrument cluster.
- List and explain the function of the various indicators found on today's vehicles.
- List and explain the function of the various warning devices found on today's vehicles.
- Explain the basics for diagnosing a gauge or warning circuit.

Every vehicle has a number of electrical instruments. The number and type, and their related parts, vary from model to model and year to year. The appearance of the instrument panel also varies from the quite simple (**Figure 21-1**) to the elaborate (**Figure 21-2**). No matter what they look like, the instrumentation must be easy to read and give accurate information. Instrument gauges, warning lights, and indicators provide valuable information to the driver concerning the vehicle's various systems.

INSTRUMENT PANELS

Today's dashboard is more properly called the **instrument panel**. It contains an array of electrical gauges, switches, and controls connected to mazes of wiring, printed circuitry, and vacuum hoses beneath stylishly finished sheets of plastic or metal.

Displays

There are many different instrument panel designs and layouts. The two basic types of instrument panel displays are analog and digital. In a traditional analog display (**Figure 21-3**), an indicator moves in front of a fixed scale to indicate a condition. The indicator is often a needle but it can also be a liquid crystal or graphic display. A digital display uses numbers instead of a needle or graphic symbol. Analog displays show relative change

Figure 21-1 A simple but functional approach to the layout of the essential gauges in an instrument panel. *Courtesy of Toyota Motor Sales, U.S.A., Inc.*

Figure 21-2 An elaborate arrangement of the essential gauges in an instrument panel. *Courtesy of Toyota Motor Sales, U.S.A., Inc.*

Figure 21-3 An analog instrument panel.

Figure 21-4 A digital instrument panel. Courtesy of Siemens VDO Automotive AG

better than digital displays (**Figure 21-4**). They are useful when the driver must see something quickly and the exact reading is not important. For example, an analog tachometer shows the rise and fall of the engine speed better than a digital display. The driver does not need to know the exact engine speed. The most important thing is how fast the engine is reaching the red line on the gauge. A digital display is better for showing exact data such as miles. Many speedometer-odometer combinations are examples of both analog (speed) and digital (distance).

Three types of digital electronic displays are used today.

Light-Emitting Diode (LED) These displays are either used as single indicator lights or they can be grouped

to show a set of letters or numbers. LED displays are commonly red, yellow, or green and can be hard to see in bright light.

Liquid Crystal Diode (LCD) These displays are made of sandwiches of special glass and liquid. A separate light source is required to make the display work. When there is no voltage, light cannot pass through the fluid. When voltage is applied, the light passes that point of the display. The action of LCDs slows down in cold weather. These displays are also very delicate and must be handled with care. Any rough handling of the display can damage it.

Vacuum Fluorescent These displays use glass tubes filled with argon or neon gas. The segments of the display are little fluorescent lights. When current is passed through the tubes, they glow very brightly. These displays are both durable and bright.

SHOP TALK

Most warning or instrument controls use **International Standards Organization (ISO)** symbols, which were developed by this organization to provide symbols easily recognizable throughout the world.

GAUGES

Gauges provide the driver with a scaled indication of the condition of a system. Two components are needed for the operation of an electrical gauge. These are instrument voltage regulators and sending units. **Instrument voltage regulators (IVRs)** are used to stabilize and limit voltage for accurate instrument operation (**Figure 21-5**). Vehicles equipped with an IVR also have a radio choke. A radio choke is a small coil of wire installed in the power lead to the IVR. The choke prevents radio interference caused by the pulsations of the IVR.

All gauges require an input from either a sending unit or a sensor. With sending or sensor units, a change or movement made by an external component causes a change in electrical resistance. Movement may be caused by pressure against a diaphragm, by heat, or by the motion of a float. In today's vehicles, the control computers and the gauges need the same information. The information passes through the computer and then to the gauge.

Figure 21-5 An IVR.

Magnetic Gauges

There are several types of magnetic gauges. The simplest form is the ammeter type (**Figure 21-6**), in which a permanent magnet attracts a ferrous indicator needle connected to a pivot point and holds it centered on the gauge. An armature, or coil of wire, is wrapped around the base of the needle near the pivot point. When current flows through the armature, a magnetic field is formed. This magnetic field opposes that of the permanent magnet. Attractive or repulsive magnetic forces cause the needle to swing left or right. The direction the needle swings depends on the direction of current flow in the armature. The needle of the gauge pivots on the armature, often called a bobbin, which is why this type of gauge is often referred to as a **bobbin gauge**.

When sending unit resistance changes, current flow through the bobbin changes, causing the

strength of the magnetic field created around the bobbin to change. As the resistance in the sending unit increases, the circuit's current decreases and a lower indicator position on the gauge results.

A **balancing coil** gauge also operates on principles of magnetic attraction and repulsion. However, a permanent magnet is not used. The base of the indicating arm is pivoted and includes an armature. Two coils are used to create magnetic fields (**Figure 21-7**).

The two coils are connected so that electricity can flow through either one. When the resistance of the sending unit is low, the right-hand coil receives more current than the left-hand coil, attracting the armature. Thus, the gauge needle moves to the right.

When the resistance of the sending unit is high, the left-hand coil receives more current. More magnetic force is created in the left-hand coil and the needle swings to the left.

Thermal or Bimetallic Gauge

A bimetallic or **thermal gauge** operates through heat created by current flow (**Figure 21-8**). A variable-resistance sending unit causes different

Figure 21-6 A simple ammeter that relies on magnetic principles.

Figure 21-7 A balancing coil gauge. Courtesy of Ford Motor Company

Figure 21-8 Typical bimetallic fuel gauge circuit.
Courtesy of Chrysler LLC

amounts of current to flow through a heating coil within a gauge. The heat acts on a bimetallic spring attached to a gauge needle. When more heat is created, the needle swings farther up the scale. When less heat is created, the needle moves down the scale.

Diagnosis

If all gauges fail to operate properly, begin by checking the circuit's fuse. Next, test for voltage at the last point common to all the malfunctioning gauges. If voltage is not present, work toward the battery to find the fault.

If the system uses an IVR, use a voltmeter to test for regulated voltage at a point common to all the gauges. If the voltage is out of specifications, check the ground circuit of the IVR. If that is good, replace the IVR. If there is no voltage present at the common point, check for voltage on the battery side of the IVR. If voltage is present at this point, replace the IVR. If regulated voltage is within specifications, test the circuit from the IVR to the gauges.

WARNING!

Many instruments and warning devices are linked to the vehicle's body control module and multiplexing network. Before troubleshooting a gauge or warning system, check the service manual to identify any special procedures or precautions.

BASIC INFORMATION GAUGES

The following gauges are found on nearly all instrument panels. The detailed operation of some gauges is described in other chapters of this book.

Speedometer

In the past, the speedometer was considered a non-electrical or mechanical gauge. It had a drive cable attached to a gear in the transmission that turned a magnet inside a cup-shaped metal piece. The cup was attached to a needle, which was held at zero by a hairspring (a fine wire spring). As the cable rotated faster with an increase in speed, magnetic forces acted on the cup and forced it to move. As a result, the needle moved up the speed scale.

Electric speedometers are used in all late-model vehicles. While there are several systems in use, one of the most common types receives its speed information from the transmission-mounted vehicle speed sensor (**Figure 21-9**). This speed signal is also used by other modules in the vehicle, including the speed control module, ride control module, the engine control module, and others.

For each 40,000 pulses from the vehicle speed sensor (VSS), the trip and total odometers will increase by 1 mile. Speed is determined by dividing the input pulse frequency (in hertz) by 2.2 hertz/mph. The circuit electronics are calibrated to drive the pointer to a location in proportion to the speed input frequency. That is, as the pulse rate increases, the speedometer records it on an analog display. This display may be limited to a maximum of 85 mph or 199 km/h.

Most digital speedometers have a speed limit. If vehicle speed exceeds these values, the speedometer continues to display the top of its range. Vehicle speed is displayed whether the vehicle is moving forward or backward.

Odometer

A mechanical odometer is driven by a spiral gear cut on the speedometer's magnetic shaft. The odometer's numbered drums are geared so that when any one drum finishes a complete revolution, the drum to the left is turned one-tenth of a revolution. On some systems, a stepper motor is used to drive the odometer. The motor receives signals from the PCM and causes the odometer to move in steps.

An electronic odometer receives its information from the VSS. Odometers display seven digits, with the last digit in tenths of a unit. The accumulated mileage value of the digital display odometer is stored in a nonvolatile read-only memory (ROM) that retains the mileage even if the battery is disconnected.

Figure 21-9 The signals from the VSS are shared by the instrument panel and the PCM.

Because the odometer records the number of miles or kilometers a vehicle has traveled, federal laws require that if a speedometer is replaced, the new odometer must be set to the same distance as was registered on the old one.

Trip Odometer This is part of the normal odometer. It records the distance traveled in intervals. The driver activates this gauge and it can be reset to zero whenever the driver desires.

Diagnosis If the speedometer or odometer is not working, the operation of the VSS should be checked before anything else. If the sensor is working fine, check the wiring from the sensor to the gauge. If all checks out, replace the speedometer/odometer assembly.

Oil Pressure Gauge

The oil pressure gauge indicates engine oil pressure. The oil pressure typically should be between 45 and 70 psi when the engine is running at a specified engine

speed and at operating temperature. A lower pressure is normal at low idle speed.

With low oil pressure (or with the engine shut off), the oil pressure switch is open and no current flows through the gauge winding. The needle points to L. With oil pressure above a specific limit, the switch closes and current flows through the gauge winding to ground. A resistor limits current flow through the winding and ensures that the needle points to about mid-scale with normal oil pressure.

A piezoresistive sensor (**Figure 21-10**) is threaded into the oil delivery passage of the engine. The pressure of the oil causes a flexible diaphragm to move. This movement is transferred to a contact arm that slides down the resistor. The position of the sliding contact arm determines the resistance value and the amount of current flow through the gauge.

Diagnosis To test a piezoresistive-type sending unit, connect an ohmmeter to the sending unit's terminal and to ground. Check the resistance with the engine off and compare it to specifications. Start the engine

Figure 21-10 A piezoresistive sensor used for measuring engine oil pressure.

and allow it to idle. Check the resistance value and compare it to specifications. Before replacing the sending unit, connect a shop oil pressure gauge to confirm that the engine is producing adequate oil pressure.

This gauge indicates engine coolant temperature (ECT). It should normally indicate between C (cold) and H (hot). The sending unit is typically a negative temperature coefficient (NTC) thermistor. With low coolant temperature, sender resistance is high and the current flow to the temperature gauge winding is low (**Figure 21-11**). The needle points to C. As coolant temperature increases, sender resistance decreases and current flow increases. The needle moves toward H.

The temperature gauge on a digital panel is of the bar type with a set number of segments. The number of illuminated bars varies according to the current flow from the sending unit. With low coolant temperature, few segments are lit. As coolant temperature increases, the number of illuminated segments increases.

Diagnosis To test a coolant temperature sending unit, use an ohmmeter to measure resistance across the terminals (**Figure 21-12**). The resistance value of the NTC thermistor decreases with an increase in temperature. Compare your measurements with the manufacturer's specifications. On most new vehicles, the action of an ECT can be monitored on a scan tool.

Fuel Level Gauge

The fuel level gauge indicates the fuel level in the fuel tank. It is a magnetic indicating system that can be found on either an analog (meter) or digital (bars) instrument panel.

Figure 21-11 Most engine coolant temperature sensors use an NTC thermistor. The resistance of an NTC decreases with an increase in temperature.

Figure 21-12 Testing a temperature sensor with an ohmmeter.

The fuel sending unit is combined with the fuel pump assembly and consists of a variable resistor controlled by the level of an attached float in the fuel tank (**Figure 21-13**). When the fuel level is low, resistance in the sender is low and movement of the gauge needle or number of lit bars is minimal (from empty position). When the fuel level is high, the resistance in the sender is high and movement of the gauge indicator (from the empty position) or number of lit bars on a digital display is greater.

Figure 21-13 A fuel gauge sending unit.

In some fuel gauge systems, an antislosh/**low fuel warning (LFW)** module is used to reduce fuel gauge needle fluctuation caused by fuel motion in the tank and provide a low fuel warning when the fuel tank reaches $\frac{1}{8}$ to $\frac{1}{16}$ full.

Photo Sequence 19 covers a typical procedure for bench testing a fuel gauge sending unit.

SHOP TALK

Some technicians use a universal gauge tester (Figure 21-14) to diagnose fuel and other gauge problems. With this tester, it is possible to manually control the inputs to a gauge and observe its reaction. The tester can also check an IVR.

Figure 21-14 A universal gauge tester.

Chapter 19 for more information on charging indicators.

Tachometer

The **tachometer** indicates engine rpm (engine speed). The electrical pulses to the tachometer typically come from the ignition module or PCM. The tachometer, using a balanced coil gauge, converts these impulses to rpm that can be read. The faster the engine rotates, the greater the number of impulses from the coil. Consequently, higher engine speeds are indicated.

In vehicles with digital instrumentation, the bar system is used with numbered segments. The numbers represent the engine's rpm times 1,000.

Charging Gauges

These allow the driver to monitor the charging system. Whereas a few older cars use an ammeter, most charging systems use a voltmeter or an indicator light. The indicator lamp will light when the voltage from the charging system is less than voltage at the battery.

INDICATOR AND WARNING DEVICES

Vehicles are equipped with several warning devices to alert the driver to problems. Most of these are safety or emissions related.

Indicator and Warning Lights

Indicator lights inform the driver that something that is normally off is now on, or vice versa. Consider the rear window defogger. When it is turned on, the indicator is lit. Another example is traction control. This system is normally on and when it is switched off, its indicator is lit. Warning lights notify the driver that something in the system is not functioning properly or that a situation exists that must be corrected. Some warning lights come on briefly when the engine is first

Bench Testing a Fuel Gauge Sending Unit

P19-1 The tools required to perform this task are a DMM, jumper wires, and a service manual.

P19-2 Select the ohmmeter function of the DMM.

P19-3 Connect the DMM's negative test lead to the ground terminal of the sending unit.

P19-4 Connect the meter's positive lead to the variable resistor terminal.

P19-5 Holding the sender unit in its normal position, place the float rod against the empty stop.

P19-6 Read the ohmmeter and check the results with the specifications.

P19-7 Slowly move the float toward the full stop while observing the ohmmeter. The resistance change should be smooth and consistent.

P19-8 Check the resistance value while holding the float against the full stop. Check the results with the specifications.

P19-9 Check the float to be sure it is not filled with fuel, distorted, or loose.

Figure 21-15 Most warning lights and indicators go through a bulb check when the ignition is first switched to the *on* position.

started; this is a bulb check (Figure 21-15). Gauges and warning lights often work together to alert the driver to a problem.

Some of the more common indicator and warning lights are described here.

WARNING!

Be aware that many of the warning and indicator lamps found on today's vehicles are triggered by a PCM or BCM. Often they are part of the multiplexed system. With this in mind, always refer to the testing methods recommended by the manufacturer before testing these systems. Using conventional testing methods on a computerized system may destroy part or all of the system.

Air Bag Readiness Light The air bag readiness light lets the driver know the air bag system is working and ready to do its job. It lights briefly when the ignition is turned on. A malfunction in the air bag system will cause the light to stay on continuously or to flash.

Fasten Belts Indicator This lamp, typically accompanied by a chime, will illuminate when the driver has not fastened the seat belt. The chime and lamp will stay on until the belt is buckled. When the ignition switch is in the *on* position, the system is activated for about 5 seconds, whether or not the driver's belt is buckled.

Figure 21-16 A TPM warning light signaling low tire pressure.

Tire Pressure Monitor (TPM) When a low-inflated or flat tire is found, this warning light will be turned on. Some systems will illuminate this warning lamp in red or yellow. Red means there is an excessively low or flat tire and yellow means a tire has low pressure (Figure 21-16). Some systems also emit a sound to alert the driver.

PROCEDURE

When the TPM light is on, follow these steps to identify why:

1. Check the tires for the proper inflation pressures.
2. Check the vehicle for nonstock accessories, such as tires, wheels, or devices that transmit radio waves, which could affect the operation of the TPM system.
3. Inspect the tires for physical damage or missing parts, such as the valve stem caps.
4. Check the tires for the presence of tire sealant. Tire sealants can block the sensor's pressure-sensing port.
5. With a scan tool, check the pressures that are being inputted to the receiver and compare those with the actual pressures.
6. Check the communication between the sensors and the receiver with a TPM diagnostic tool.

Brake Warning Light When this light is lit, it is an indication that the parking brake is engaged or there is a problem with the brake system. Vehicles built for Canada may have a separate warning lamp that indicates when the parking brake is applied.

Brake Fluid Level Warning Light The lamp is connected to a brake fluid level sensor in the brake fluid reservoir. If the brake fluid drops below a specified level, the sensor is activated and the light turns on while the engine is running.

Antilock Light If an antilock brake system fault is present, the antilock brake module grounds the indicator circuit, and the antilock light goes on. Vehicles built for Canada may have a different symbol on their warning lamp.

Brake Pad Indicator This lamp illuminates when the sensors at the wheel brake units sense thin brake pads. The sensors are typically embedded in the pads and when they contact the metal rotor, the warning light circuit is complete and the lamp is lit.

Stoplight Warning Light The light is controlled by a stoplight checker. The checker has a reed switch and magnetic coils. Magnetic fields form around the coils by the current flowing through each light when the stoplight switch is on. The magnetic fields cancel each other because the coils are wound in opposite directions. As a result, the reed switch and the warning light are off. If a stoplight fails, current only flows through one coil, and the resultant magnetic field causes the reed switch to close and the warning light to illuminate when the brake pedal is depressed.

Traction/Stability Control Lamp This lamp is illuminated in red when there is a problem with the traction and/or stability control systems. The red lamps will also be lit when the system is turned off. Yellow lamps are lit when the system is actively regulating drive torque and braking force (Figure 21–17).

Figure 21-17 The traction control, brake system, and ABS indicators and warning lamps.

Check Engine Light This may be also labeled as “Service Engine Soon.” This warning is primarily an emissions-related light. If something happens that will cause the vehicle to have higher emissions, the PCM will display this warning. This warning may also be triggered by oil pressure or coolant temperature. This warning may illuminate when the computer has stored a fault or diagnostic code in its memory.

Oil Pressure Light This lamp is operated by an oil pressure switch located in the engine’s lubricating system. Some vehicles will illuminate this lamp in yellow or red to indicate the action the driver should take, red meaning the engine has an oil pressure problem and the engine should be shut down and yellow indicating the oil level is low and should be topped off as soon as possible.

Charge Indicator Light If there is something wrong with the charging system, this light comes on while the engine is running.

Check Filler Cap This lamp will be illuminated when the gas filler cap is not tight or off and when the engine control system senses a problem with the fuel system.

Low Fuel Warning This lamp will illuminate when the fuel level is below a quarter full. An electronic switch closes and power is applied to illuminate the lamp.

Add Coolant Lamp The purpose of this lamp is to inform the driver of low coolant levels in the cooling system.

Maintenance Reminder This lamp is triggered by mileage. It turns on to alert the driver that maintenance needs to be performed on the vehicle. This is not a warning; it is a reminder. Often the lamp will light for 2 seconds when the car is started, if the vehicle has been serviced within a specified interval. Normally, the required maintenance is an engine oil change. The name of this indicator includes “oil” on many vehicles. When the lamp is not reset during the specified distance, it will flash after the engine has started. If there was no service for about twice the recommended distance, the lamp will stay on continuously until it is reset.

The procedure for resetting this reminder varies by manufacturer. The following procedure should serve only as an example. To reset the reminder on a vehicle, refer to the service information for the vehicle being serviced.

PROCEDURE

To reset the maintenance reminder on a late-model Honda:

1. Turn the ignition switch on.
2. Press the ODO/TRIP switch until the trip meter A appears.
3. Turn the ignition switch off.
4. Then turn the ignition switch back on while pressing the trip odometer reset knob.
5. Hold the reset knob down for about 30 seconds. The reminder lamp should go out during that time.

Transmission Indicator This is part of an automatic transmission's control system. If the system detects a fault, it may operate the transmission in the fail-safe mode and will illuminate the warning light to inform the driver of the problem and to alert him or her that the transmission may not be working normally.

Drive Indicator Some four-wheel-drive vehicles have a lamp which, when lit, indicates that the vehicle is in four-wheel-drive mode of operation.

O/D Off Indicator This lamp is illuminated when the overdrive function of an automatic transmission has been switched off by the driver.

Rear Defrost Indicator When this light is lit, the defroster or deicer is operating.

High-Beam Indicator With the headlights turned on and the main light switch dimmer switch in the high-beam position, the indicator illuminates.

Left and Right Turn Indicators With the multifunction switch in the left or right turn position, voltage is applied to the circuit to illuminate the left or right turn indicator. The turn indicator flashes in unison with the exterior turn signal bulbs.

Fog Light Indicator This lamp is illuminated when the fog lights are turned on.

Lamp-Out Warning The lamp-out warning module is an electronic unit that is designed to measure small changes in voltage levels. An electronic switch in the module closes to complete a ground path for the indicator lights in the event of a bulb going out.

The key to this system being able to detect one bulb out on a multibulb system is the use of the special resistance wires. With bulbs operating, the resistance wires provide 0.5 volt input to the light-out warning module. If one bulb in a particular system goes out, the input off the resistance wire drops to approximately 0.25 volt. The light-out warning module detects this difference and completes a ground path to the indicator light for the affected circuit.

Cruise Control Light This lamp is lit whenever the cruise control is turned on.

Air Suspension Light Voltage is present at the air suspension indicator at all times. If an air suspension fault exists, the ground of the light circuit is closed and the indicator illuminates.

Door Ajar Warning When the ignition is turned on and if the doors are left open or are ajar, this light comes on.

Add Washer Fluid Lamp Obviously, the purpose of this lamp is to inform the driver of a low level in the windshield washer fluid reservoir.

Sound Warning Devices

Various types of tone generators, including buzzers, chimes, and voice synthesizers, are used to remind drivers of a number of vehicle conditions. These warnings can include fasten seat belts, air bag operational, key left in ignition, door ajar, and light left on. **Figure 21-18** is a tone generator system schematic.

Park Distance Control (PDC) This feature uses sensors to measure the distance the front and/or rear of the vehicle is from an object (**Figure 21-19**). An audible signal changes in frequency as the vehicle gets closer to an object. As the distance between the vehicle and object decreases, the intervals between the tones become shorter. When the object is very close, the tone is emitted continuously. The system uses four ultrasonic sensors at the rear and the front of the vehicle. Some systems include a visual indication of the distances to the obstacles, in addition to the audible warning.

Some systems allow the front sensors to be manually turned off in special situations such as stop-and-go traffic. The rear sensors automatically turn on when the transmission is placed into reverse.

DRIVER INFORMATION CENTERS

The various gauges, warning devices, and comfort controls may be grouped together into a driver information center or instrument cluster. This may be simple (Figure 21-20) or an all-encompassing cluster of information. The message center keeps the driver alert of the information available. The types and extent of this information varies from one system to another.

Figure 21-20 Information for the driver appears across the bottom of the instrument cluster. Courtesy of Toyota Motor Sales, U.S.A., Inc.

In addition to standard warning signals, the information center may provide such vital data as fuel range, average or instantaneous fuel economy, fuel used since reset, time, date, estimated time of arrival (ETA), distance to destination, elapsed time since rest, average car speed, percent of oil life remaining, and various engine-operating parameters.

Other electronic displays and controls can be found on today's vehicles.

Heads-Up Display

A **heads-up display (HUD)** projects visual images onto the windshield using a vacuum fluorescent light source to complement in-dash instrumentation (Figure 21-21). Because these images are projected in the driver's field of vision, the driver does not need to remove his or her eyes from the road to see certain

Figure 21-21 The heads-up display (HUD) can project the vehicle's speed onto the windshield, freeing the driver from looking down at the speedometer. Courtesy of Siemens VDO Automotive AG

pertinent information. Among the images HUD may display are vehicle speed, turn-signal indicators, low fuel warning, and a high-beam indicator. HUD systems use a prismatic mirror to project their images, a clean windshield, and dim ambient lighting to allow the driver to see the display.

Graphic Displays

Graphic displays are translucent drawings of the vehicle. They have small lamps located at various spots in the graphic. When a lamp is lit, the area indicated by the lamp has a problem. These indicators can note such things as the trunk is open or a light bulb is not working.

Hybrid Vehicles

Hybrid vehicles have some unique and interesting warnings, indicators, and displays. They all also have normal displays for the engine and other systems. The following is a brief look at the unique stuff they have.

Honda The instrument panel on most Honda hybrids displays the typical conditions for a gasoline engine, plus they display the operation of the hybrid (IMA) system and the car's fuel efficiency. Also, on cars with a manual transmission, the panel has upshift and downshift lights that are triggered by the PCM to inform the driver when it is most economical to shift gears.

The instrument panel has a meter that displays the status of the battery and IMA system (**Figure 21-22**). A charge/assist indicator shows when the system's electric motor is assisting the engine. The amount of assist is indicated by bars. The number of bars illuminated indicates how much assist is being provided. This same display shows the amount of charge going to the batteries. When more bars are illuminated, the batteries are being recharged at a higher rate. Also on this side of the cluster is a state-of-charge indicator for the battery module. The entire cluster is designed to help the driver achieve maximum fuel economy.

Figure 21-22 The instrument cluster in Honda hybrid vehicles has a meter that displays the status of the battery and IMA system.

Figure 21-23 The energy monitor for a Toyota Prius. Courtesy of Toyota Motor Sales, U.S.A., Inc.

Toyota Most Toyota hybrids have a multi-information display in the center cluster panel. The display, a 7-inch LCD with a pressure sensitive touch panel, serves many functions. Many of these are typical, but some are unique to hybrid technologies. One is the fuel consumption screen. This display shows average fuel consumption, current fuel consumption, and the current amount of recovered energy.

Another unique display is the energy monitor screen (**Figure 21-23**). This shows the direction and path of energy flow through the system in real time. By observing this display, drivers can alter their driving to achieve the most efficient operation for the current conditions.

Like other vehicles, these vehicles are equipped with a variety of warning lamps and indicators. Here are some of the indicators that are unique:

- “Ready” light—This lamp turns on when the ignition switch is turned to START to indicate that the car is ready to drive.
- Output control warning light—This lamp turns on when the temperature of the HV battery is too high or low. When this lamp is lit, the system's power output is limited.
- HV battery warning light—This lamp lights when the charge of the HV battery is too low.
- Hybrid system warning light—When the HV control unit detects a problem with the motor/generators, the inverter assembly, the battery pack, or the ECU itself, this lamp will be lit.
